- **(c) Structure of the N-terminal domain of *E. coli* H-NS dimer.**

All structures show protein secondary structures and tubular DNA

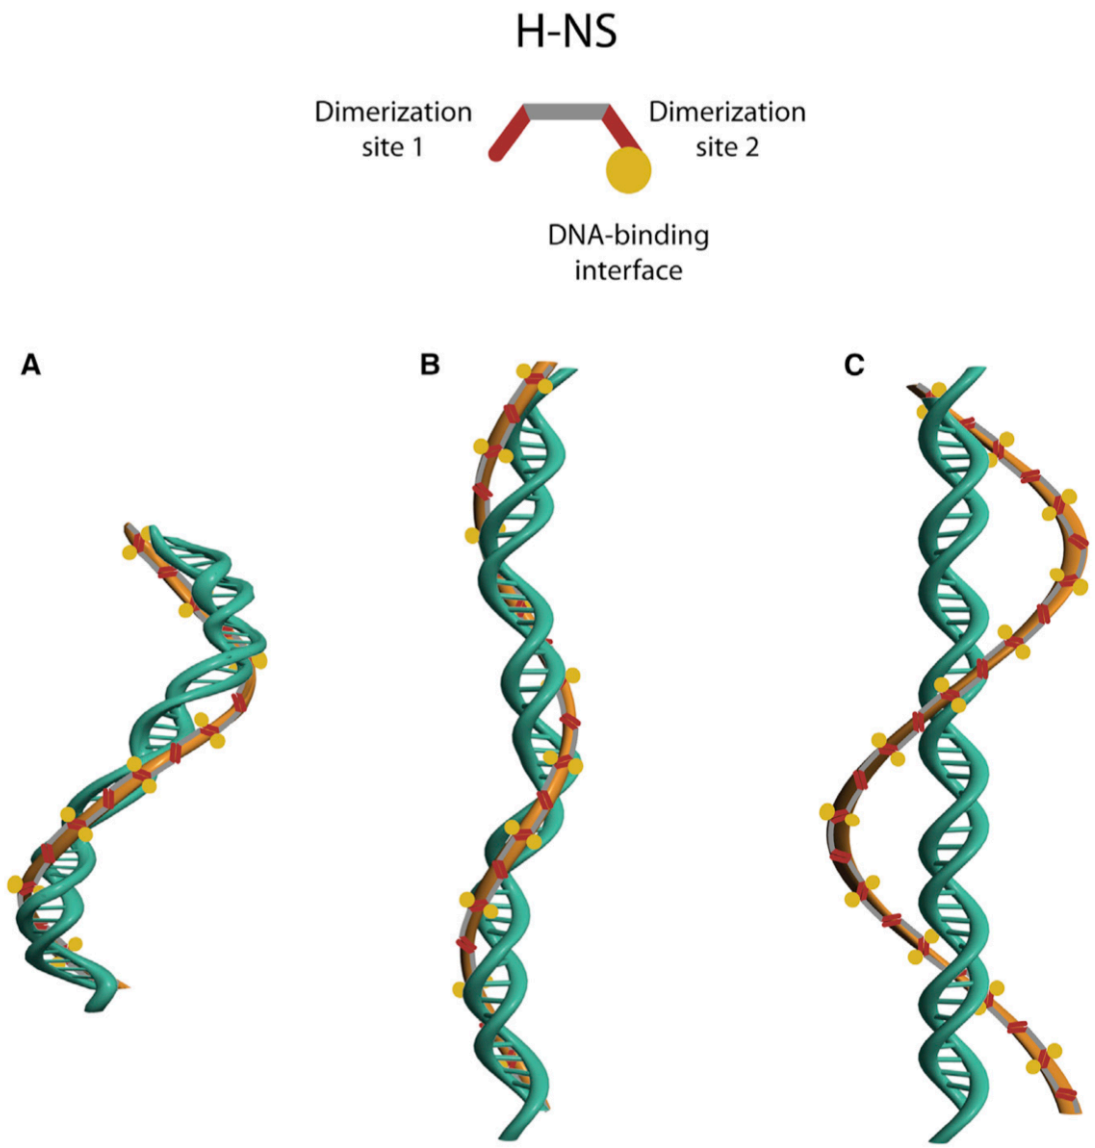

FIGURE 3 H-NS forms a right-handed helical nucleoprotein filament. An H-NS molecule has two dimerization domains (Fig. 1), which enable H-NS to form a chain of linked H-NS molecules on DNA. Three H-NS nucleoprotein filament structures are proposed. (*A*) DNA wraps around an H-NS helix, reducing the contour length to ~50%. (*B*) A flexible H-NS nucleoprotein filament allows deformation into a thinner and longer structure. (*C*) H-NS wraps around the DNA in a helix, forming thick nucleoprotein filaments. The DNA is drawn to scale to highlight the change in contour length. Yellow circles (free DNA-binding domains) that are directed toward the outside of these helical filaments may allow interaction with naked DNA, hence forming filament-mediated DNA bridges under certain conditions.

The mitochondrial histone HM: an evolutionary link between bacterial HU and nuclear HMG1 proteins.

Megraw TL, Kao LR, Chae CB.

Department of Biochemistry and Biophysics, University of North Carolina, Chapel Hill 27599-7260, USA.

Abstract

The mitochondrial histone HM is a very abundant protein in yeast mitochondria that wraps DNA and activates transcription in vitro and is required within the cell for proper maintenance of the mitochondrial chromosome. HM and the bacterial histone-like protein HU have similar activities in vitro and can substitute for each other in E coli cells and in yeast mitochondria. HM also appears to be functionally homologous to nuclear HMG1 proteins, with which it shares a high degree of sequence homology. We report here the isolation of extragenic suppressors of the yeast HM mutant temperature-sensitive phenotype. We also examined the effects of the lack of HM protein and of respiration deficiency on yeast cells mutant for the NHP6 proteins, the putative yeast nuclear HMG1 homologues.

Protein Components of Mitochondrial DNA Nucleoids in Higher Eukaryotes*

Daniel F. Bogenhagen‡§, Yousong Wang‡, Ellen L. Shen‡¶, and Ryuji Kobayashi‖**

Mitochondrial DNA (mtDNA) is not packaged in nucleosomal particles, but has been reported to associate with the mitochondrial inner membrane. Gentle lysis of *Xenopus* oocyte mitochondria with nonionic detergent liberates a nucleoprotein complex containing mtDNA associated with a previously characterized DNA binding partner, mitochondrial transcription factor A (mtTFA), as well as a series of inner membrane proteins identified by sequencing. More extensive detergent treatment stripped most of these proteins from the DNA, leaving a limited number of proteins in a nucleoid core. Sequencing of the major proteins retained in association with mtDNA revealed the expected mtDNA binding proteins, mtTFA and mitochondrial single-stranded DNA binding protein (mtSSB), as well as four proteins not previously reported to associate with mtDNA. These include adenine nucleotide translocator 1, the lipoyl-containing E2 subunits of pyruvate dehydrogenase and branched chain α-ketoacid dehydrogenase and prohibitin 2. The association of several of these proteins with mtTFA-containing mtDNA nucleoids was confirmed by immunoprecipitation. ***Molecular & Cellular Proteomics 2:1205–1216, 2003.***

contrast to the wealth of information on the protein packaging of nuclear DNA in chromatin. The endosymbiotic hypothesis suggests that the DNA-protein complexes in mitochondria may resemble those in their bacterial ancestors. While eubacteria do not package their DNA in nucleosomes, they do contain abundant basic proteins like HU and INT that compact the DNA and exert a significant influence on gene expression (2).

mtDNA is associated with at least two basic proteins with clear bacterial homologs. The HMG-box protein, mitochondrial transcription factor A (mtTFA), which has been conserved from yeast to humans, is structurally related the bacterial HU protein. Indeed, the yeast mtTFA and *Escherichia coli* HU proteins can genetically substitute for one another (3). mtTFA plays a role as a transcription factor in vertebrates (4–6), but apparently not in yeast (7). Thus, it appears that the essential role that mtTFA plays in yeast mtDNA maintenance is as an architectural DNA binding protein, which accounts for its relative abundance (8). mtTFA is remarkably abundant in mitochondria of *Xenopus* oocytes and human HeLa cells, with hundreds of copies of the protein per mtDNA (5, 9–11). A second mtDNA binding protein that is relatively well-charac-

Additional examples of chromosome banding….

R-banding procedures (modified Giesma or Hoechst stain) produce the reverse, or opposite banding pattern as **G-banding** and **Q-banding** and denotes the **GC-rich, euchromatic regions**. R-bands are also important for detecting minor inversions, for comparing length of homologues, for examining the ends of chromosomes, and for identifying subtle deletions or rearrangements that may go undetected using G- or Q-bands.

Previous figure showed Q-banding.

C-banding is a procedure which stains the **constitutive heterochromatin** that is localized in **pericentromeric** regions of all chromosomes and on the distal long arm of the Y chromosome. The process is similar to G-banding (except heat is used instead of proteolytic enzymes to open up the DNA). The use of C-banding facilitates the determination of **pericentric** inversions and also the identification of polymorphisms within the **centromeric** regions of chromosomes.

NOR staining is a silver staining procedure which stains the nucleolus organizer regions (NORs) of satellited chromosomes. It is particularly useful in studying variations in the size of the stalks and satellites of the acrocentric chromosomes.

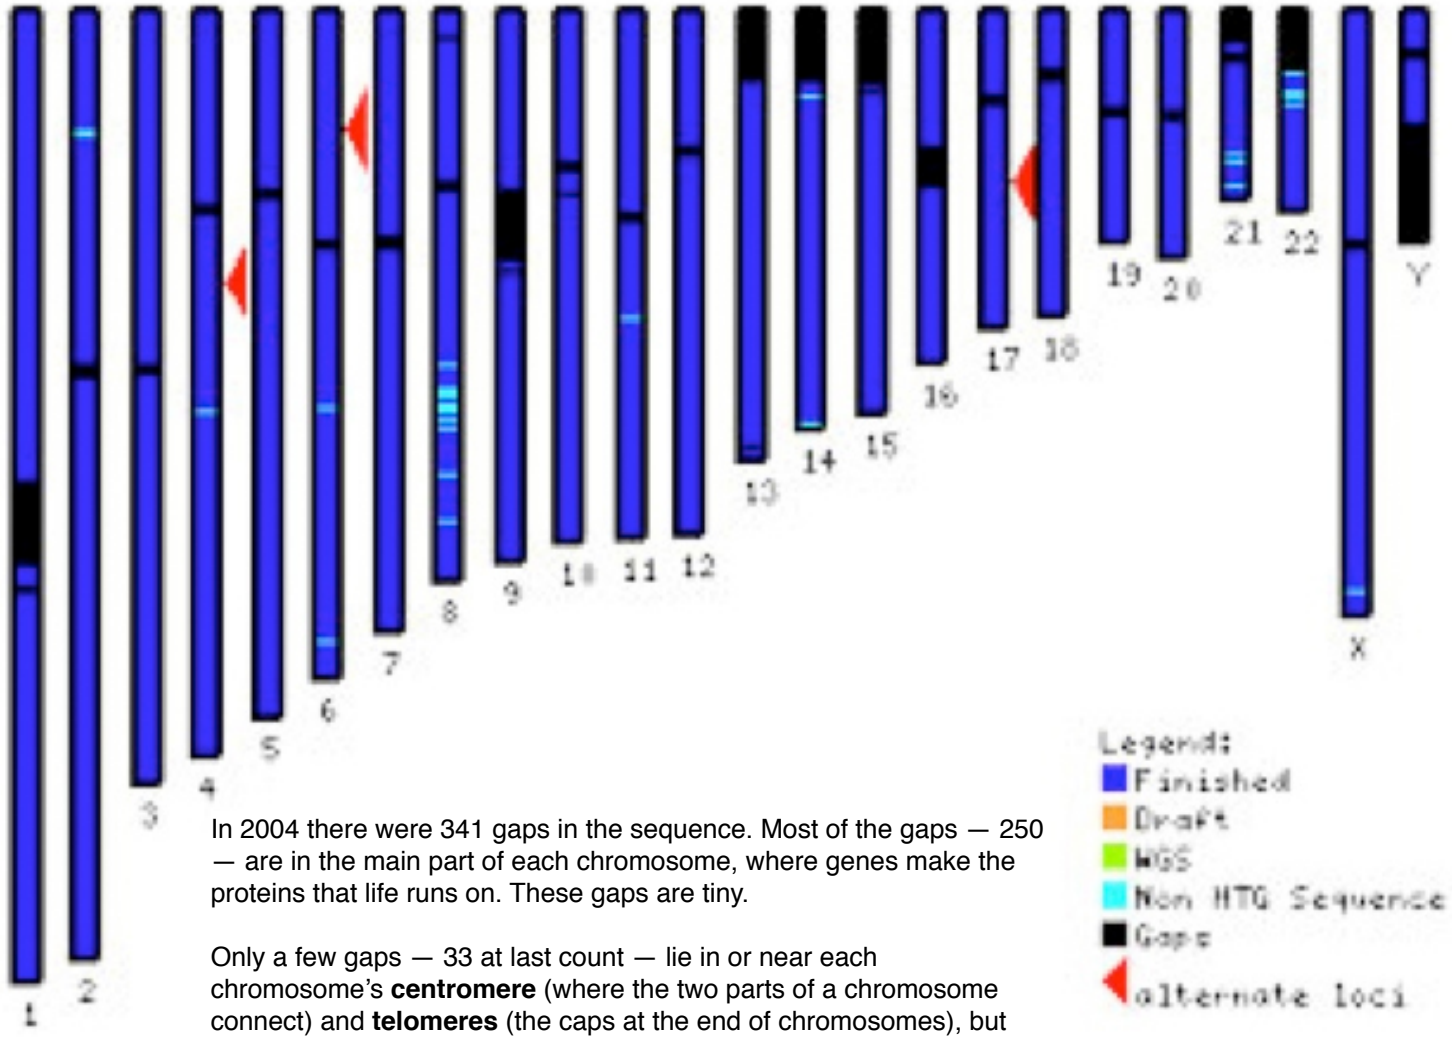
LIFE: THE SCIENCE OF BIOLOGY, Seventh Edition, Figure 9.9 Molecular Biology of Chromatid Attachment and Separation



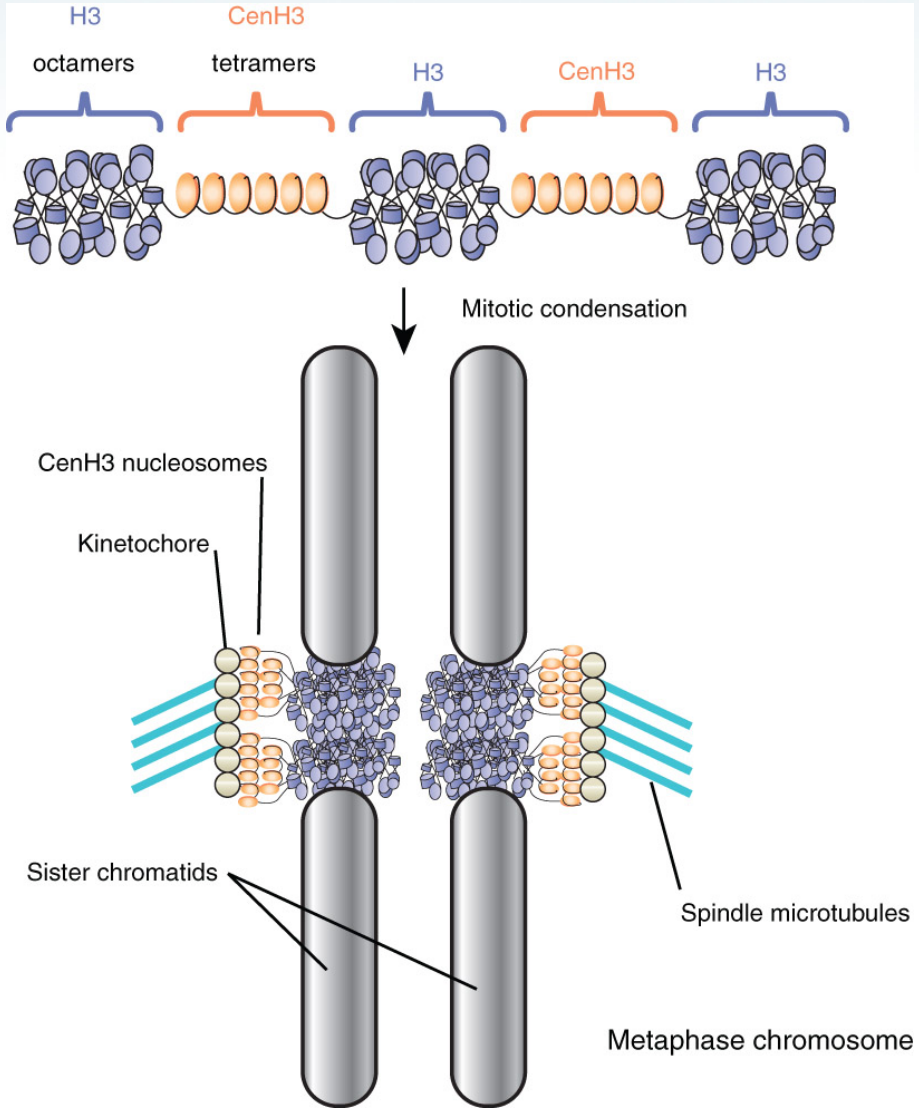
In 2004 there were 341 gaps in the sequence. Most of the gaps — 250 — are in the main part of each chromosome, where genes make the proteins that life runs on. These gaps are tiny.

Only a few gaps — 33 at last count — lie in or near each chromosome's **centromere** (where the two parts of a chromosome connect) and **telomeres** (the caps at the end of chromosomes), but these 33 are 10 times as long in total as the 250 gaps.

"It's very fair to say the human genome was never fully sequenced," Craig Ventner

"The human genome has not been completely sequenced and neither has any other mammalian genome as far as I'm aware," said Harvard Medical School bioengineer George Church, who made key early advances in sequencing technology.

Regional Centromeres Contain a Centromeric Histone H3 Variant and Repetitive DNA



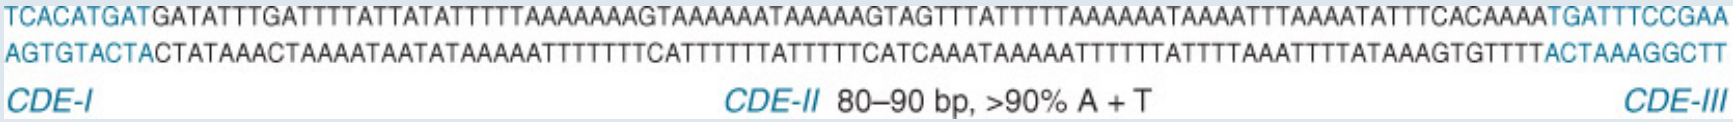
A model of the overall structure of a regional centromere

Adapted from Y. Datal, et al., Proc. Natl. Acad. Sci. USA 104 (2007): 15974-15981.

Centromeres in *S. cerevisiae* Contain Short, Essential DNA Sequences

- *CEN* elements are identified in *S. cerevisiae* by the ability to allow a plasmid to segregate accurately at mitosis.

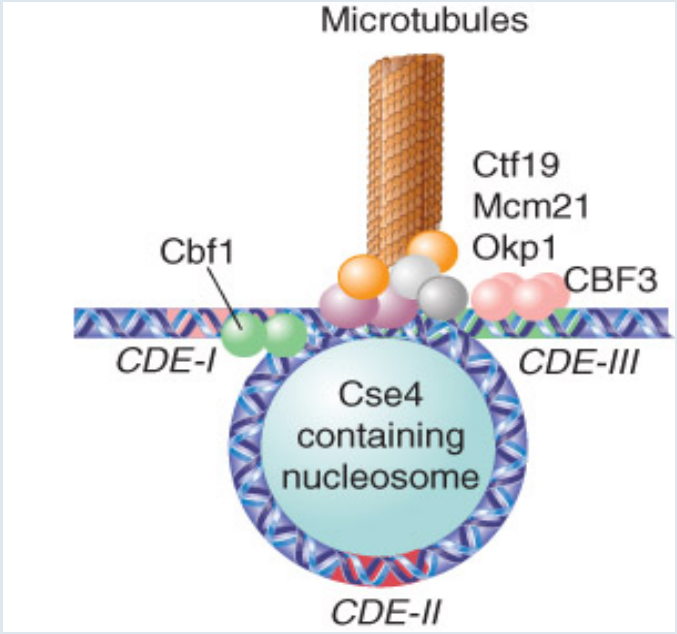
- *CEN* elements consist of the short, conserved sequences *CDE-I* and *CDE-III* that flank the A-T-rich region *CDE-II*.



Three conserved regions can be identified by the sequence homologies between yeast CEN elements.

In *S. cerevisiae* the Centromere Binds a Protein Complex

- A specialized protein complex that is an alternative to the usual chromatin structure is formed at *CDE-II*.
- The histone H3 variant Cse4 is incorporated in the centromeric nucleosome.
- The CBF3 protein complex that binds to *CDE-III* is essential for centromeric function.
- The proteins that bind *CEN* serve as an assembly platform for the kinetochore and provide the connection to microtubules.



The DNA at CDE-II is wound around an alternative nucleosome.

A unique chromatin complex occupies young α-satellite arrays of human centromeres

Abstract

The intractability of homogeneous α-satellite arrays has impeded understanding of human centromeres. Artificial centromeres are produced from higher-order repeats (HORs) present at centromere edges, although the exact sequences and chromatin conformations of centromere cores remain unknown. We use high-resolution chromatin immunoprecipitation (ChIP) of centromere components followed by clustering of sequence data as an unbiased approach to identify functional centromere sequences. We find that specific dimeric α-satellite units shared by multiple individuals dominate functional human centromeres. We identify two recently homogenized α-satellite dimers that are occupied by precisely positioned CENP-A (cenH3) nucleosomes with two ~100–base pair (bp) DNA wraps in tandem separated by a CENP-B/CENP-C–containing linker, whereas pericentromeric HORs show diffuse positioning. Precise positioning is largely maintained, whereas abundance decreases exponentially with divergence, which suggests that young α-satellite dimers with paired ~100-bp particles mediate evolution of functional human centromeres. Our unbiased strategy for identifying functional centromeric sequences should be generally applicable to tandem repeat arrays that dominate the centromeres of most eukaryotes.

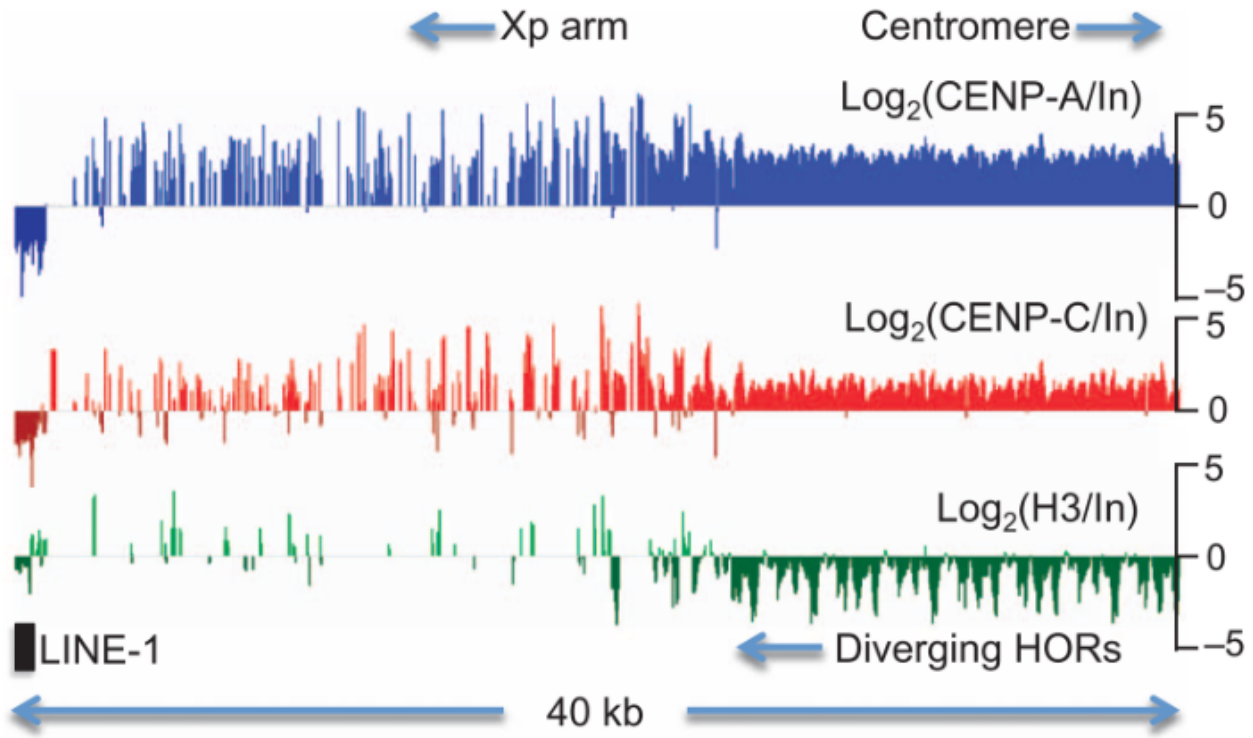

Fig. 1. CENP-A and CENP-C enrichment decreases withα-satellite divergence in pericentric heterochromatin

Log-ratio CENP-A, CENP-C, and H3 enrichment profiles spanning the 40-kb most proximal annotated segment of chromosome arm Xp, which spans the DXZ1 α-satellite HOR gradient (3). Dense CENP-A and CENP-C enrichment diminishes with distance from the centromere-proximal edge, and depletion of H3 diminishes ~20 kb from the edge. Diverged α-satellite occupies the Xp arm punctuated by LINE-1 and other elements where centromere protein enrichment is low.

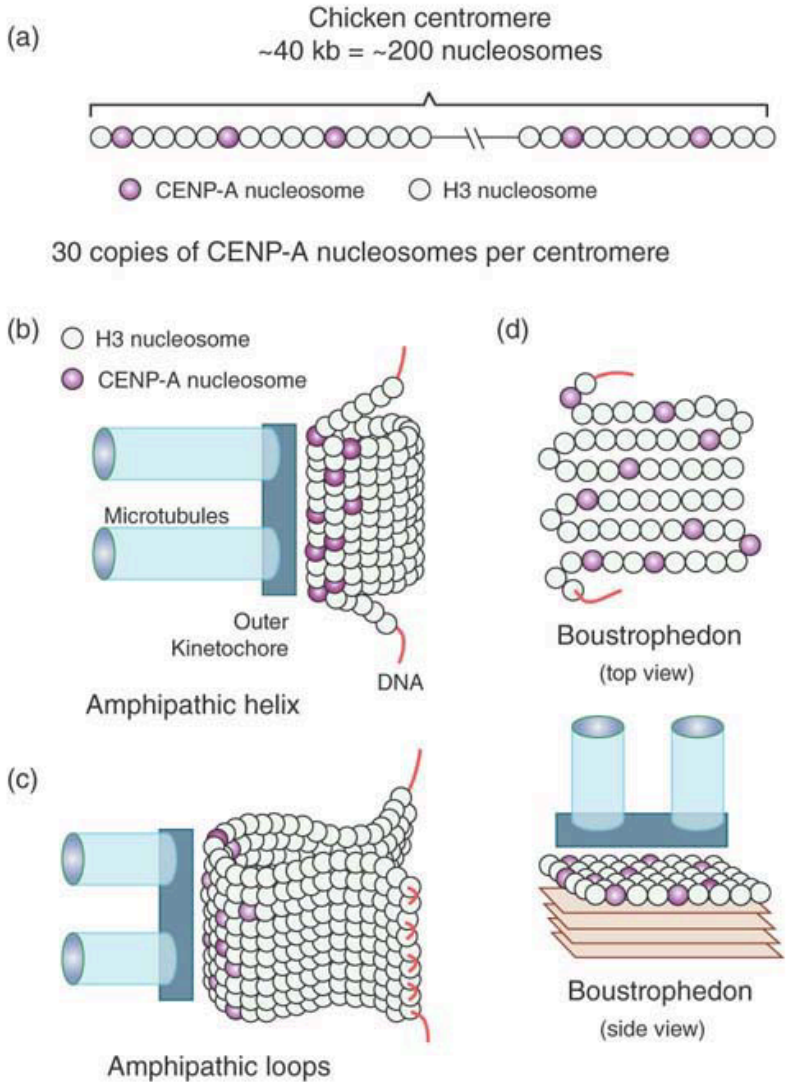

FIGURE 7.25 Organization of CENP-A and H3 Nucleosomes in Centromeres. (a) Centromeres are ~40 kb long in chicken, corresponding to 200 nucleosomes per centromere. Of these, 30 are predicted to contain CENP-A (roughly 1 in 6–8 centromeric nucleosomes). Thus, centromeric chromatin is largely composed of nucleosomes containing histone H3. (b and c) The CENP-A chromatin was originally suggested to form an amphipathic organization, with CENP-A on the exterior facing the kinetochore, and H3 largely on the interior. This chromatin was proposed to form either a helix or loop structure. (d) The boustrophedon model of centromeric CENP-A-containing chromatin was proposed based on super-resolution microscopy.

Fig. 1. Length-independent telomere damage. Telomere shortening that occurs naturally with each round of cell division ultimately leads to chromosome ends becoming exposed and activating a DNA damage response, which results in a permanent arrest known as replicative senescence. However, recent evidence suggests that telomeres may serve as highly sensitive sensors of stress. It is known that mild oxidative stress causes single-stranded breaks to accumulate at telomeres, leading to accelerate shortening and premature cell cycle arrest. However, it is possible that acute stresses induce telomeric double-stranded breaks which are not efficiently repaired. This results in a persistent DDR signaling, preventing cells from undergoing further rounds of replication irrespective of their telomere length, a state which can also be called "telomere length-independent senescence".

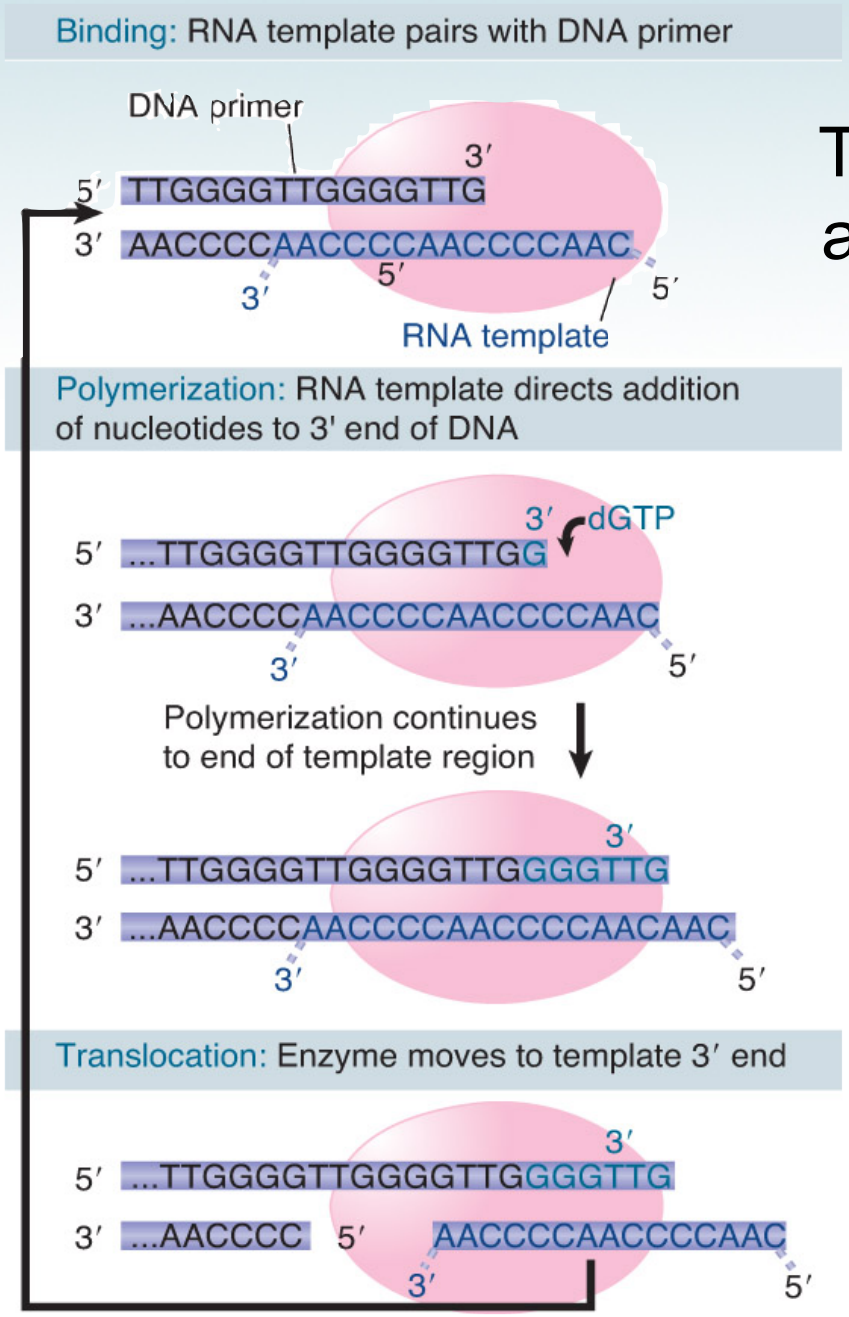
Telomeres Are Synthesized by a Ribonucleoprotein Enzyme

- **Telomerase** (TERT) uses the 3′–OH of the G+T telomeric strand to prime synthesis of tandem TTGGGG repeats (in Ciliates) and TTAGGG in humans.

- The RNA component of telomerase (TE**RC**) is a sequence of RNA of varying length (159 bases - 451 bases) and has a sequence that pairs with the C+A-rich repeats at the end of chromosomes.

- One of the protein subunits within the TERT is a reverse transcriptase that uses the RNA as template to synthesis the G+T-rich sequence (RNA Dependent DNA Polymerase; RDDP).

Telomeres Are Synthesized by a Ribonucleoprotein Enzyme, Telomerase (TERT)



Telomerase positions itself by base pairing between the RNA template and the protruding single-stranded DNA primer

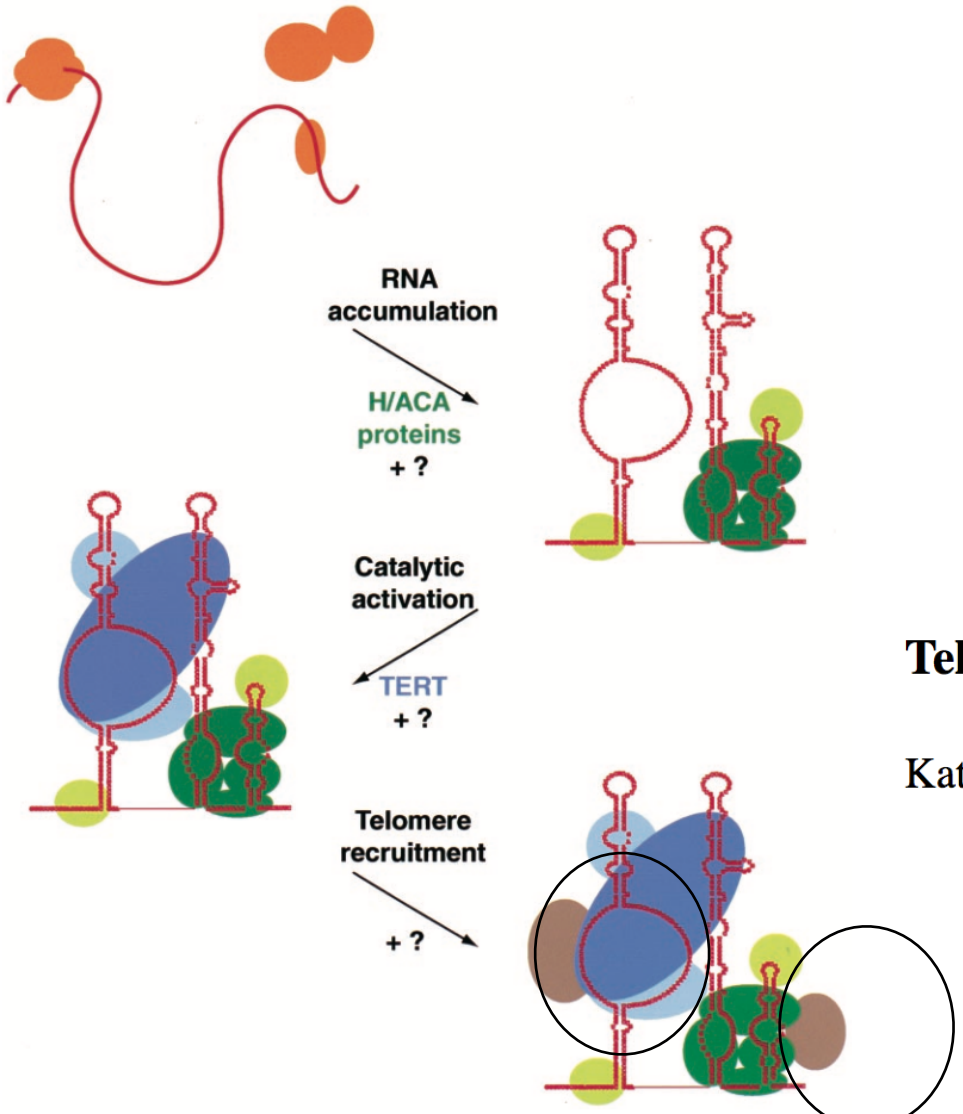


Figure 1 Biogenesis of biologically active human telomerase enzyme. Step 1: telomerase RNA synthesis and maturation require the participation of numerous cellular factors, which together will establish the level of mature RNA accumulation. Some factors (orange) will associate only transiently with telomerase RNA (red). H/ACA proteins (darker green) and other hTR binding proteins (lighter green) become bound to telomerase RNA, providing RNA stability. Step 2: catalytic activation requires the association of telomerase RNP with TERT (dark blue) and possibly other proteins as well (lighter blue). TERT binds directly to telomerase RNA in at least two separable regions. Step 3: active holoenzyme must be recruited to telomere substrates. Proteins that interact with active telomerase (brown) may regulate its recruitment to telomeres by interacting with telomeric chromatin directly or by affecting telomerase subnuclear localization

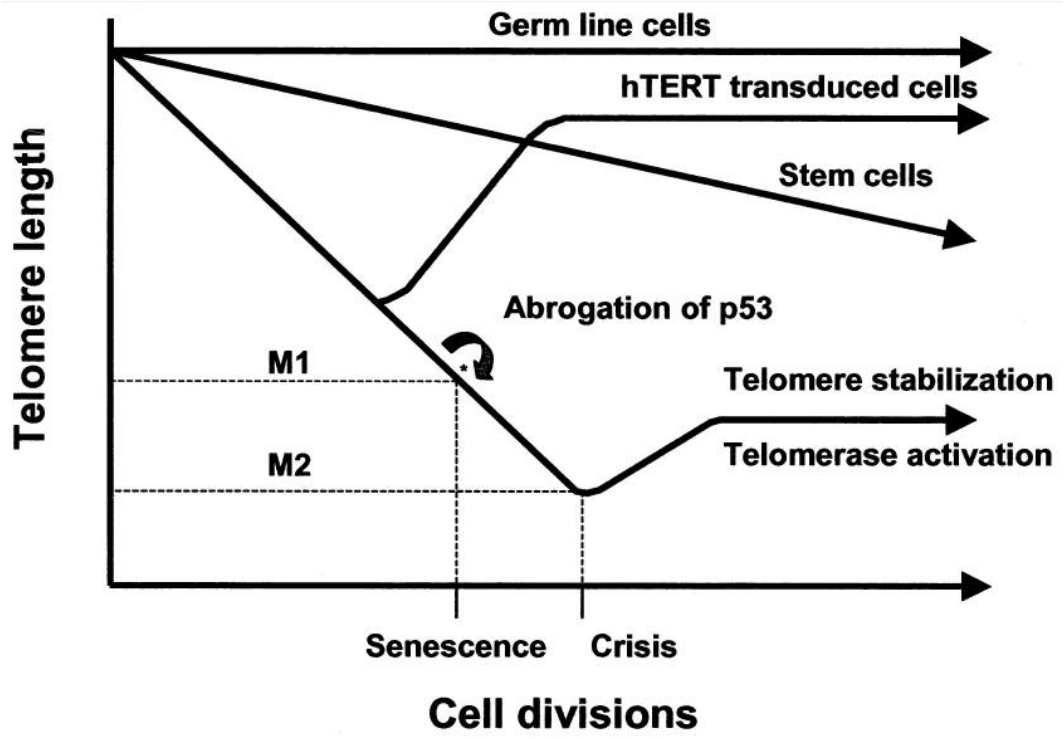
Telomerase in the human organism

Kathleen Collins and James R Mitchell[a]



Two-step hypothesis of cellular senescence and immortalization. Unlike **germ cells,** in which telomere length is maintained by telomerase, most human somatic cells have lower levels of telomerase or are telomerase negative and experience telomere shortening with each cell division.

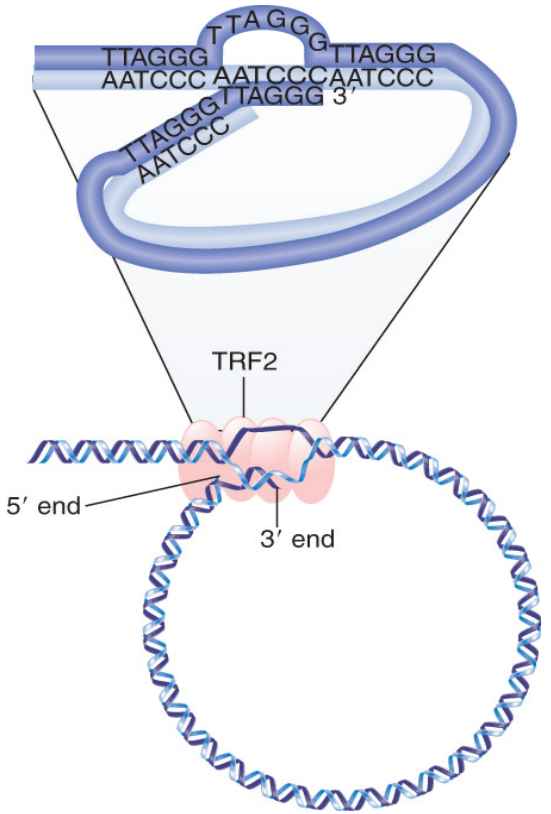
Pluripotent stem cells are **telomerase positive** -but DO NOT necessarily maintain full telomere length.
Telomere length shortens in stem cells at rates slower than that of telomerase-negative somatic cells.
Critically shortened telomeres may signal cells to enter senescence at, what is called the "**Hayflick limit",** or "**M1"**.

This proliferative checkpoint can be overcome by inactivation of **pRB/p16** or **p53**.
Such cells continue to suffer telomere erosion and ultimately enter crisis, or **M2**, characterized by widespread cell death. Rarely surviving cells acquire unlimited proliferative potential and stabilization of telomere length by reactivation of telomerase.

When cells are cultured in adequate conditions, ectopic expression of hTERT allows cells to bypass proliferation barriers and become immortal.

Telomeres Seal the Chromosome Ends and Function in Meiotic Chromosome Pairing

- The protein **TRF2** catalyzes a reaction in which the 3′ repeating unit of the G+T-rich strand forms a loop upstream of the end of the chromosome by displacing its homolog in an upstream region of the telomere -forming a D-loop.



A loop forms at the end of chromosomal DNA

Photo courtesy of Jack Griffith, University of North Carolina at Chapel Hill.

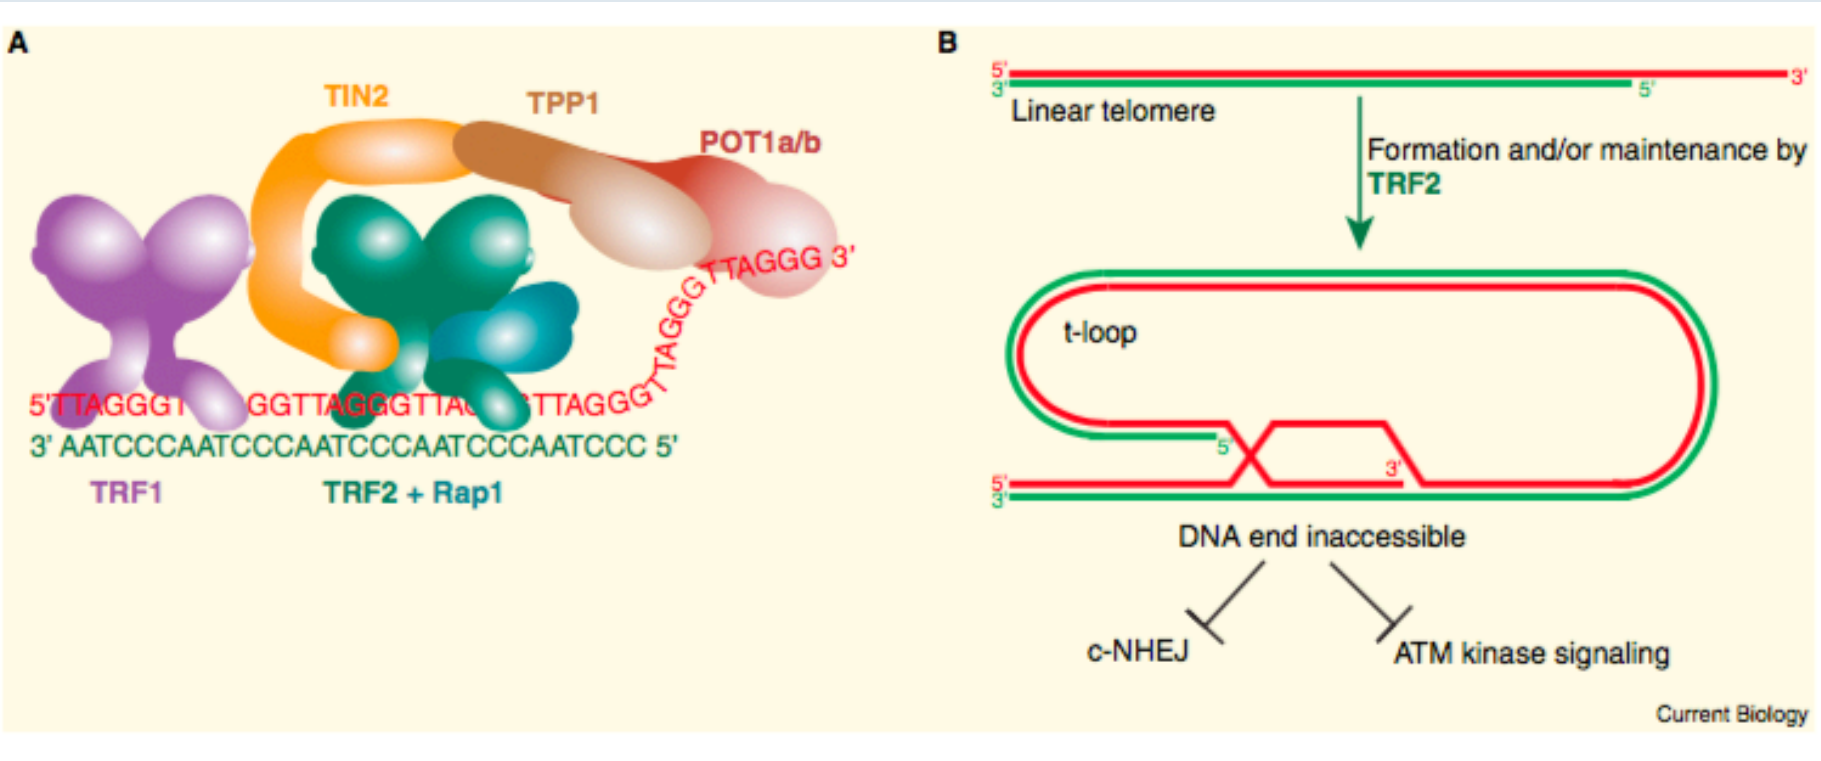


Figure 1. The shelterin complex protects telomeres from DNA damage signaling and repair.

At mammalian telomeres, the presence of shelterin (A) ensures genome integrity by repressing DNA damage signaling and repair, promoting semi- conservative replication of the telomeric DNA, and regulating telomerase-mediated telomere maintenance. The t-loop structure (B) is crucial for repression of c-NHEJ and ATM kinase signaling.

Current Biology 26, R387–R407, May 23, 2016

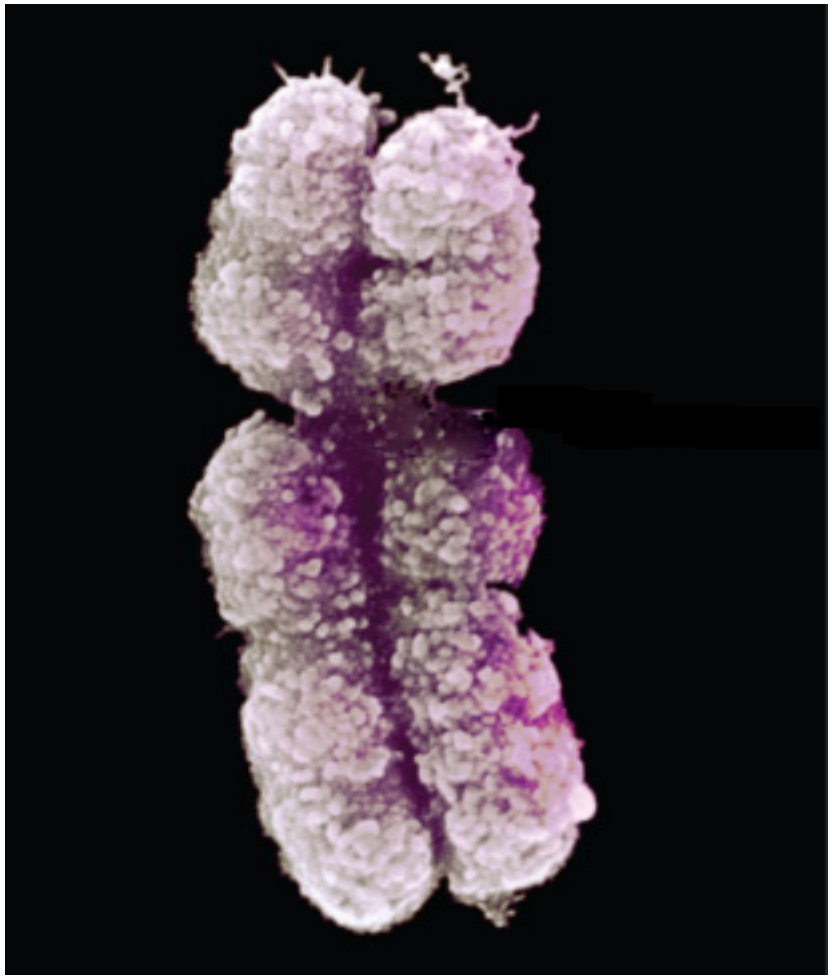
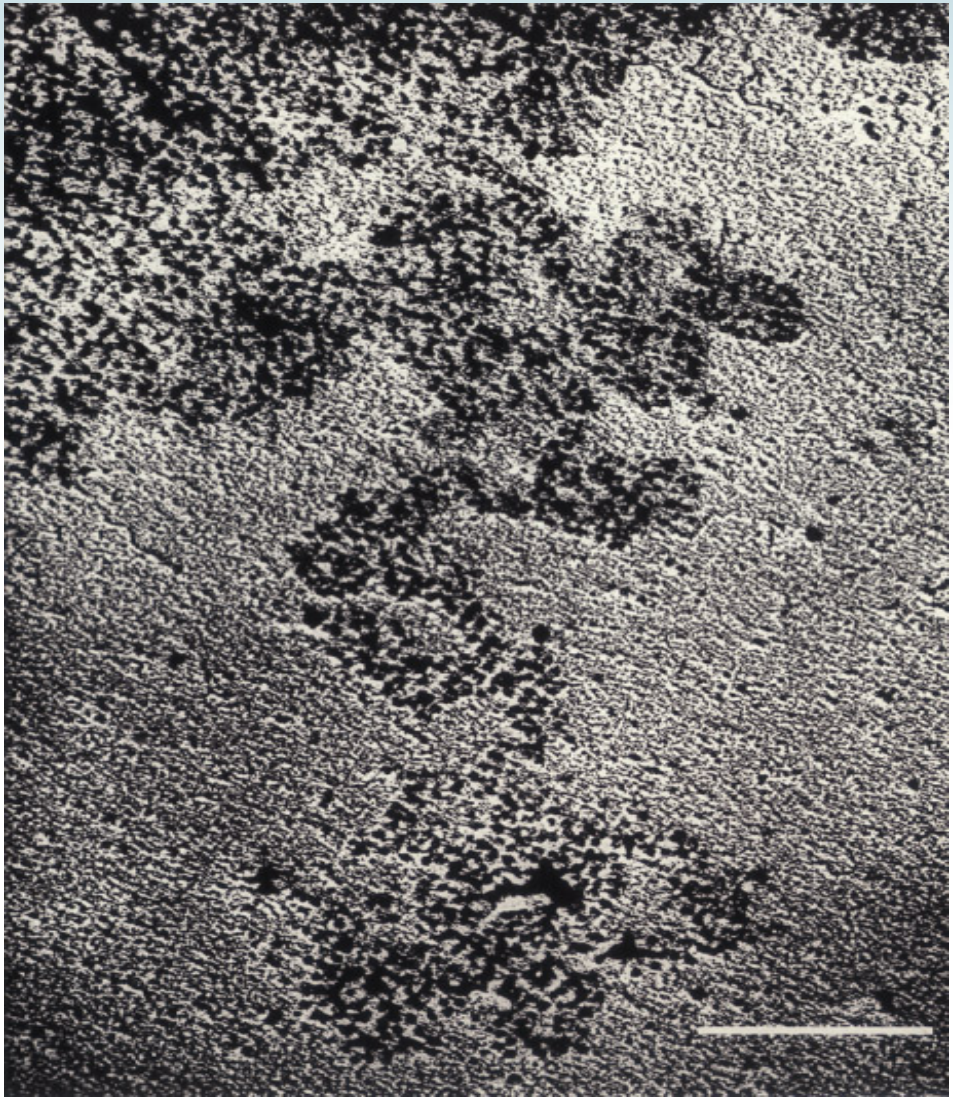
The Eukaryotic chromosome



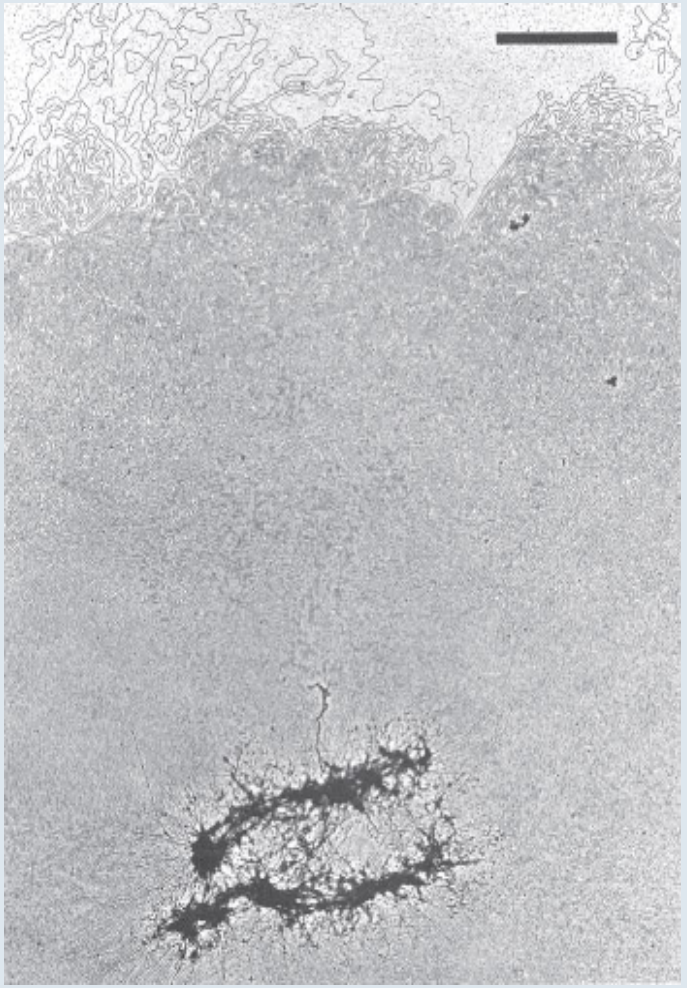
- Organized Structures -banding
- Centromeres
- Telomeres
- **Nucleosomes**
- **Euchromatin / Heterochromatin**



Chromatin spilling out of lysed nuclei consists of a compactly organized series of particles. The bar is 100 nm

- DNA of interphase chromatin is negatively supercoiled into independent domains of ~85 kb.

- Metaphase chromosomes have a protein **scaffold** to which the loops of supercoiled DNA are attached.



Histone-depleted chromosomes consist of a protein scaffold to which loops of DNA are anchored.

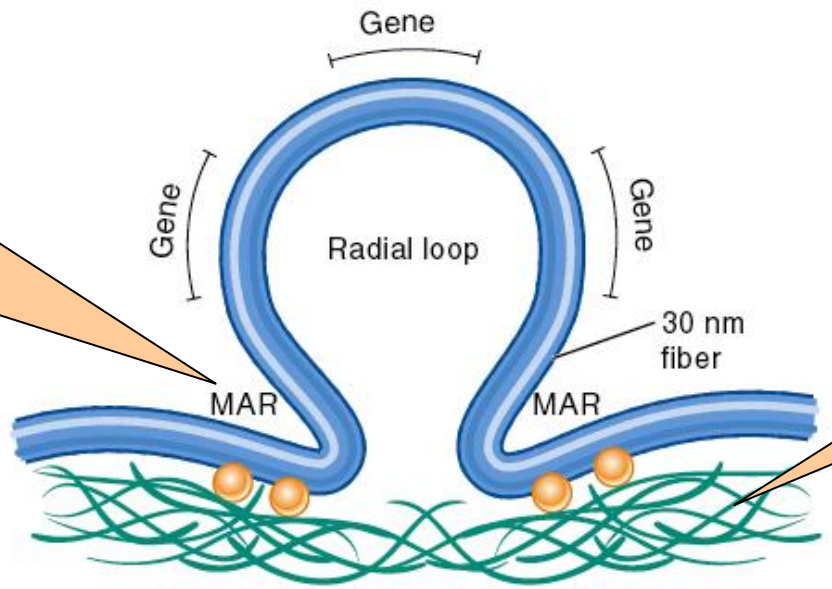
Further Compaction of the Chromosome

- An additional level of compaction involves interaction between the 30 nm fibers and the nuclear matrix

Matrix-attachment regions

or

Scaffold-attachment regions (SARs)



MARs are anchored to the nuclear matrix, thus creating radial loops

Specific Sequences Attach DNA to an Interphase Matrix

- DNA is attached to the nuclear matrix at specific sequences called **MARs** or **SARs**.
- The MARs are A-T-rich but do not have any specific consensus sequence.
- **Chromosome scaffold –** A proteinaceous structure in the shape of a sister chromatid pair, generated when chromosomes are depleted of histones.

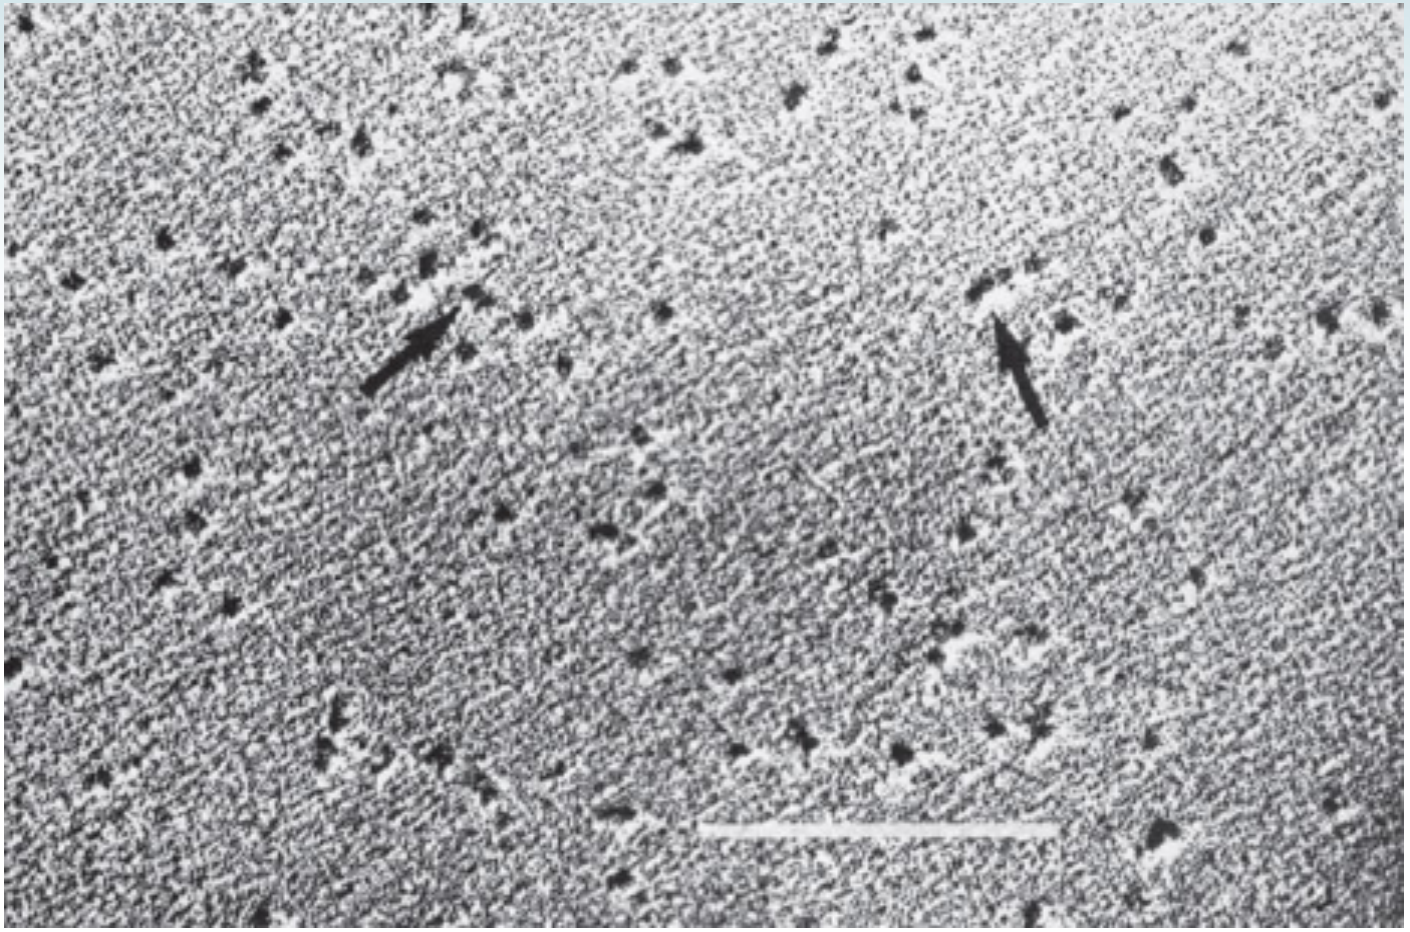
Brooker, Fig 12.6



Individual nucleosomes are released by digestion of chromatin with micrococcal nuclease. The bar is 100 nm

There are effectively **five classes of histones**.

The core of a nucleosome contains eight histone molecules, two each from four of the histone classes.

There are **147 - 160 base pairs** of DNA wrapped around the core, or >1.65 turns of DNA.

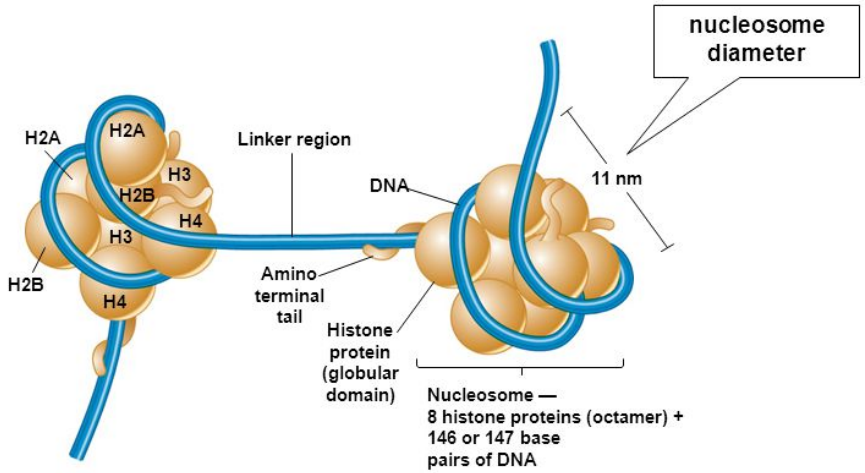
One molecule from the remaining histone class, histone **H1**, clamps the DNA to the core, and helps form the next level of packaging.

During **mitosis** and **meiosis**, the **chromatin** becomes even more heavily coiled and condensed.

Regions of chromatin that remain densely packed throughout interphase are termed **heterochromatin.**

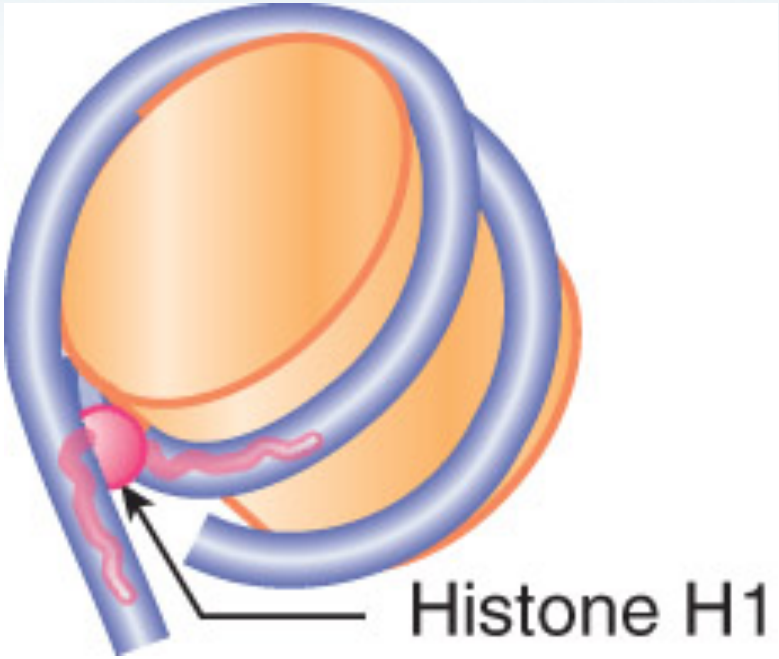
Chromocenter – An aggregate of heterochromatin from different chromosomes.

Nucleosomes shorten DNA ~seven-fold



(a) Nucleosomes showing core histone proteins

Brooker, Fig 12.10a



- Linker DNA is the region of 8 to 114 bp, and this is the region that is susceptible to early cleavage by the enzyme.
- Changes in the length of linker DNA account for the variation in total length of nucleosomal DNA.
- H1 proteins are associated with linker DNA and may lie at the point where DNA enters and leaves the nucleosome.

Possible model for the interaction of **histone H1** with the nucleosome

table 24–3

Types and Properties of Histones

Histone	Molecular weight	Number of amino acid residues	Content of basic amino acids (% of total)	
			Lys	Arg

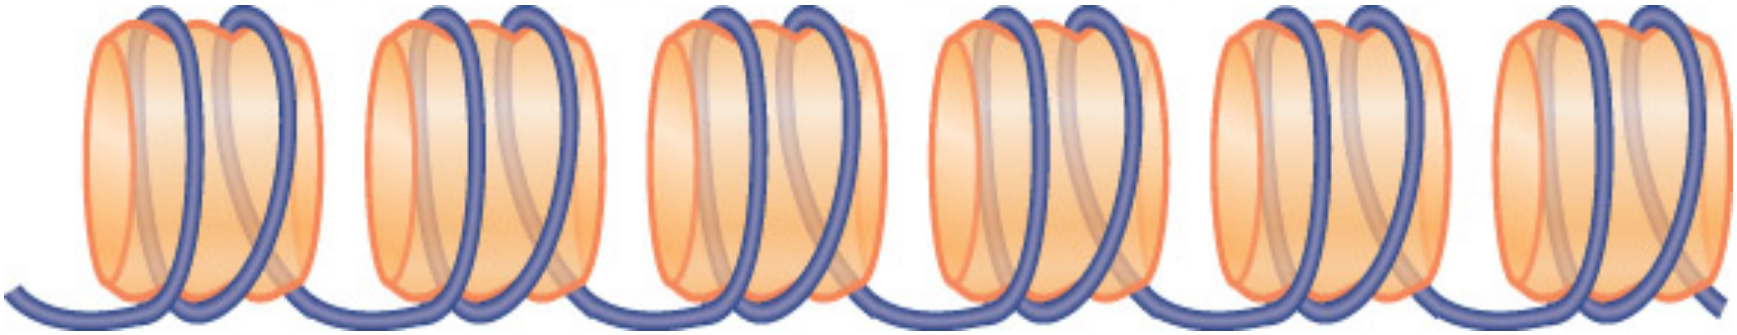
LIFE: THE SCIENCE OF BIOLOGY, Seventh Edition, Figure 9.6 DNA Packs into a Mitotic Chromosome

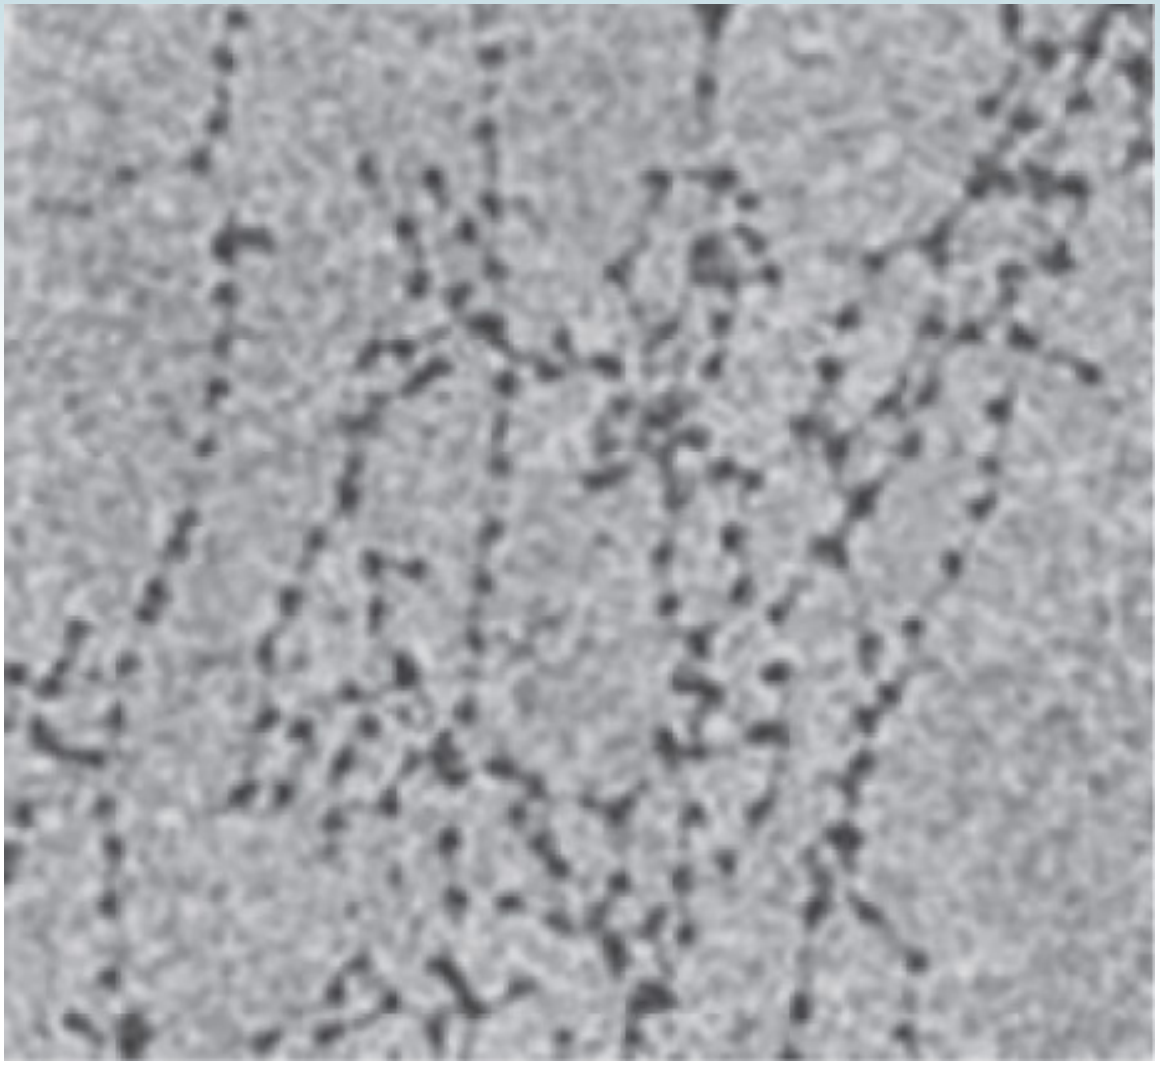
Chromatin: Basic Structures

- **nucleosome –** The basic structural subunit of chromatin, consisting of ~200 bp of DNA wrapped around an octamer of **histone** proteins.

- **histone tails** – Flexible amino- or carboxy-terminal regions of the core histones that extend beyond the surface of the nucleosome.
  - Histone tails are sites of extensive post translational modification.



The 10 nm fiber is a continuous string of nucleosomes



The 10 nm fiber in partially unwound state can be seen to consist of a string of nucleosomes

Photo courtesy of Barbara Hamkalo, University of California, Irvine.

Chromatin: Basic Structures

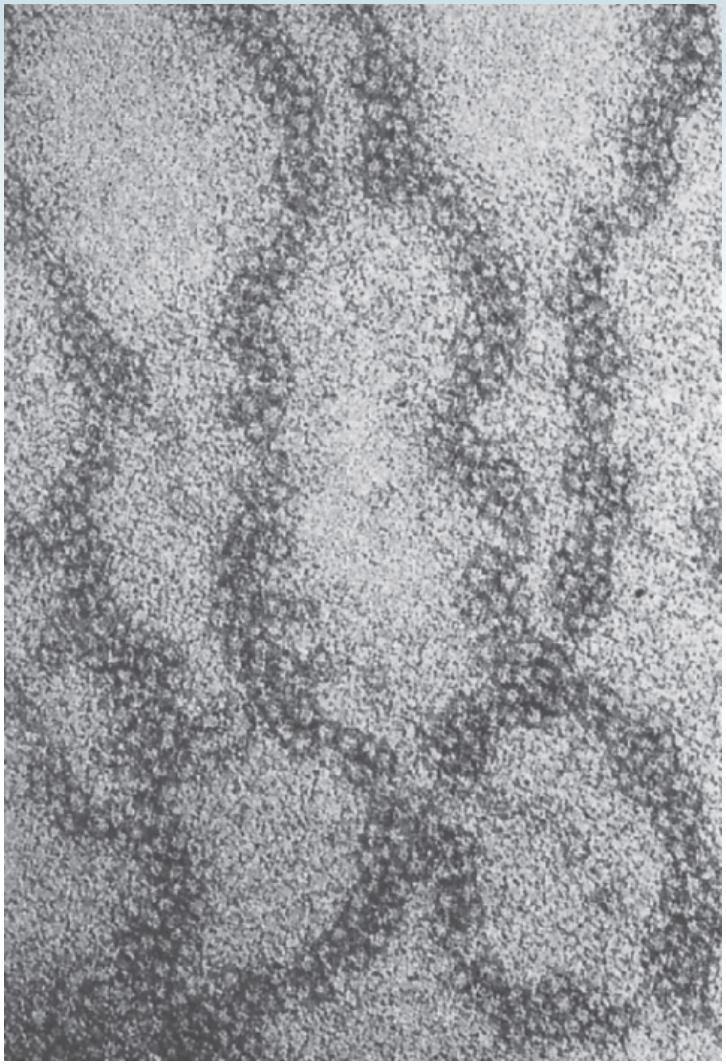
- **10 nm fiber** – a linear array of nucleosomes generated by unfolding from the natural condition of chromatin.

- **linker histones** – a family of histones (substantially the histone **H1 family**) that are NOT components of the nucleosome core.
  - Linker histones bind nucleosomes and/or linker DNA and promote formation of the **30 nm fiber**s.

Chromatin: Basic Structures

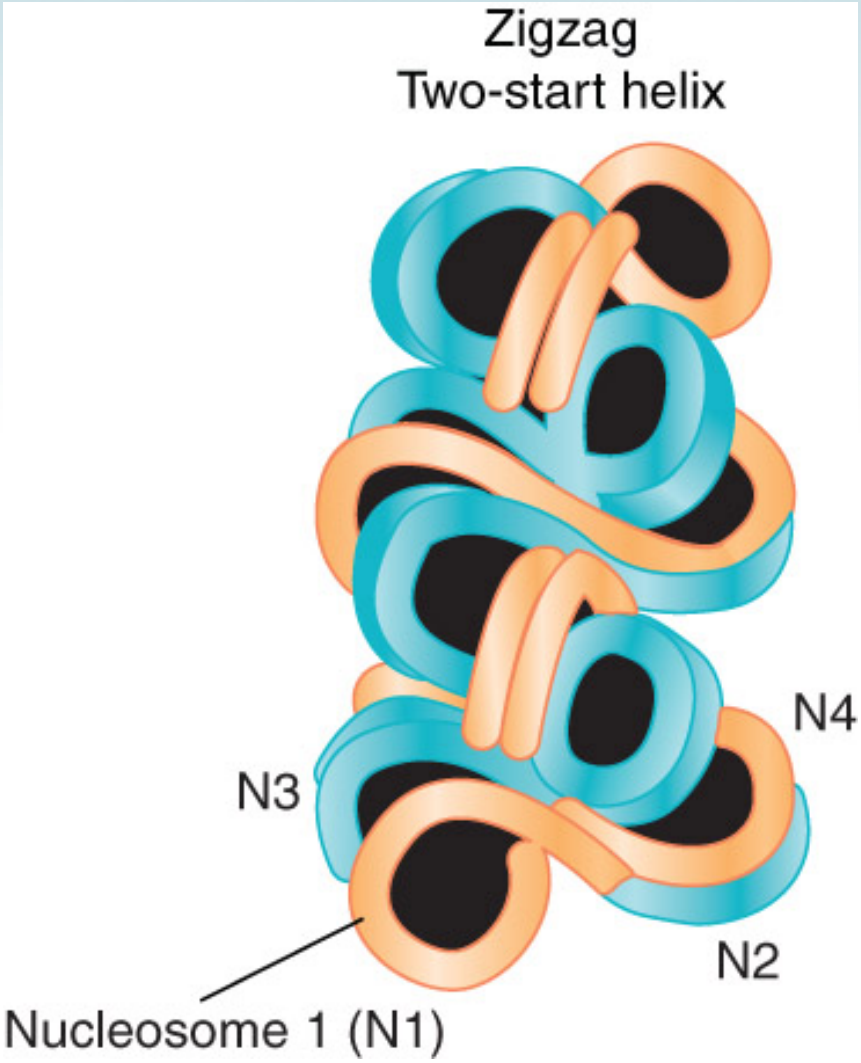
- **30 nm fiber** – A coil of nucleosomes.
  - It is the basic level of organization of nucleosomes in chromatin.

- **nonhistone** – Any structural protein found within a chromosome with the exception of histones.



The 30 nm fiber has a coiled structure

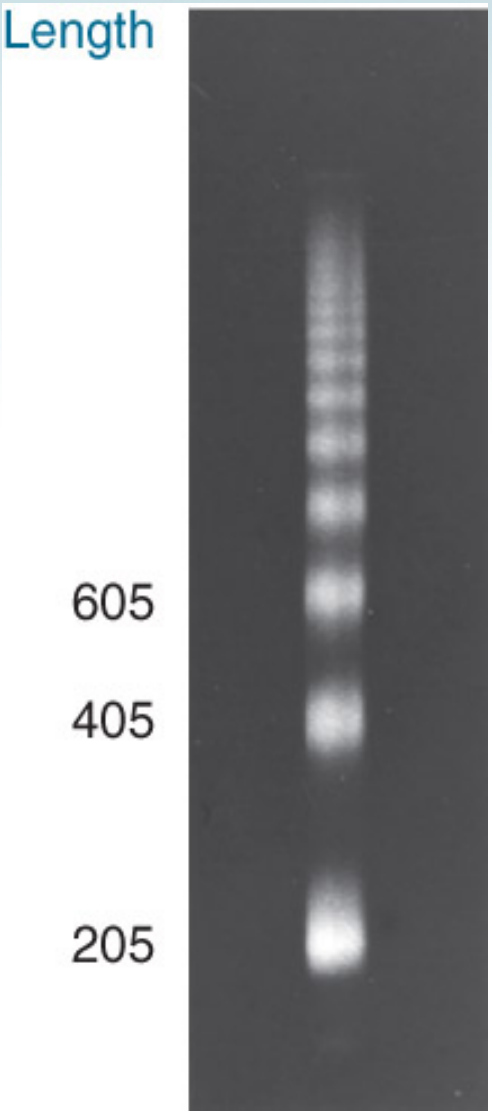
Photo courtesy of Barbara Hamkalo, University of California, Irvine.

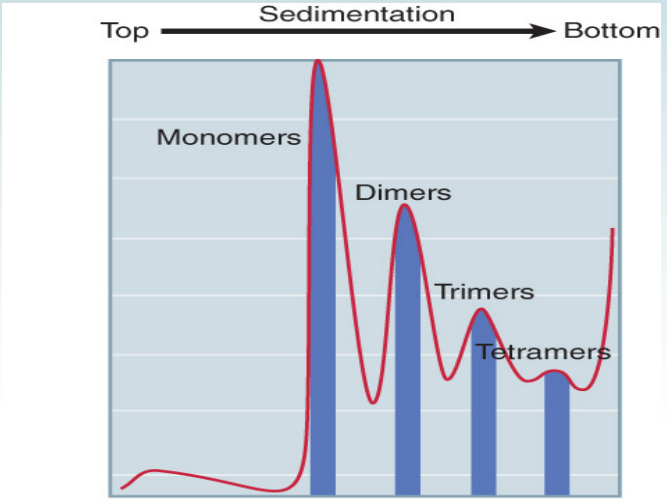


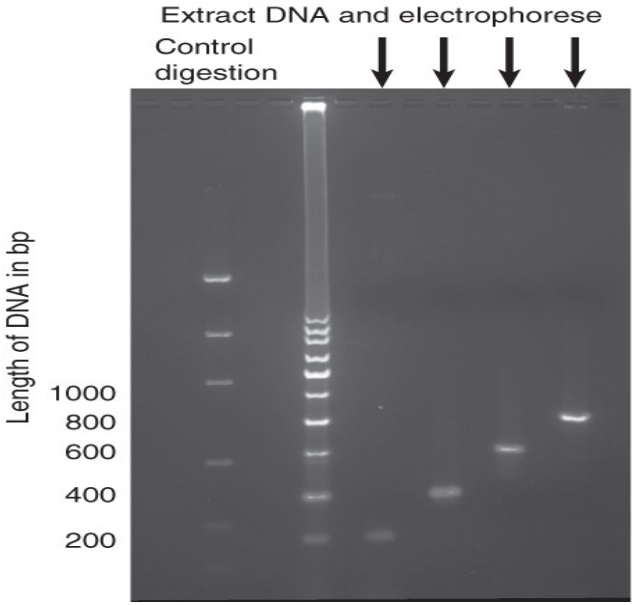
The 30 nm fiber is a two start helix consisting of two rows of nucleosomes coiled into a solenoid

DNA Is Organized in Arrays of Nucleosomes

- **MNase (micrococcal nuclease)** cleaves linker DNA and releases individual nucleosomes from chromatin.
- >95% of the DNA is recovered in nucleosomes or multimers when **MNase** cleaves DNA in chromatin.
- The length of DNA per nucleosome varies for individual tissues or species in a range from **154** to **260 bp**.
- Nucleosomal DNA is divided into the core DNA and linker DNA depending on its susceptibility to MNase.







Micrococcal nuclease digests chromatin in nuclei into a multimeric series of DNA bands that can be separated by gel electrophoresis. Each multimer of nucleosomes contains the appropriate number of unit lengths of DNA

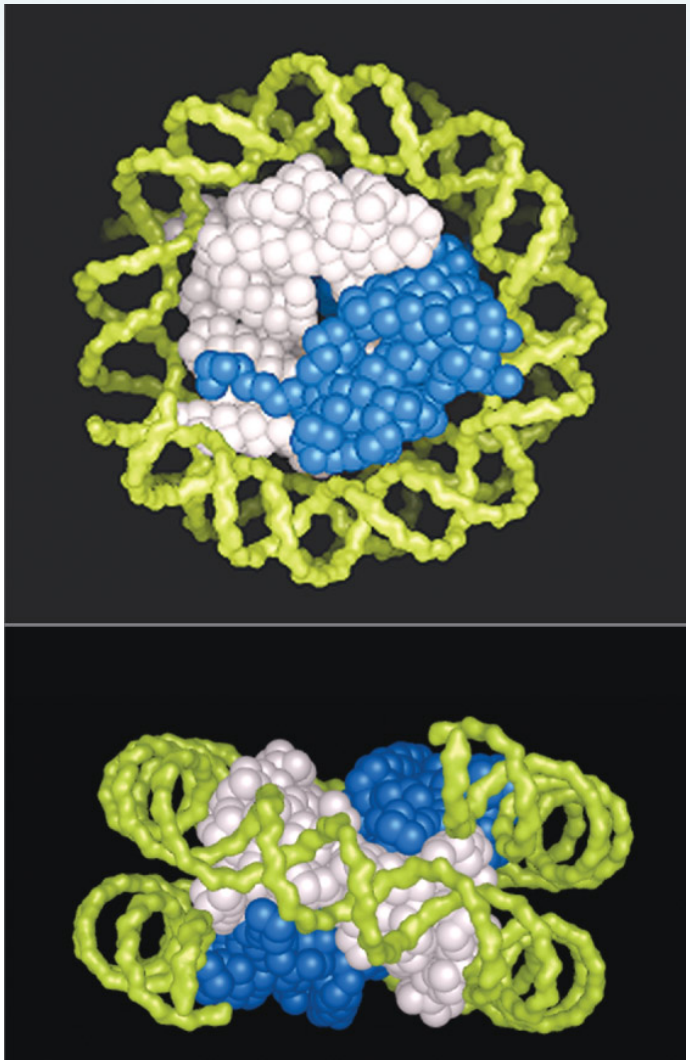
Most modified sites in histones have a single, specific type of modification, but some sites can have more than one type of modification

The Nucleosome Is the Basic Subunit of All Chromatin

- Each histone is extensively interdigitated with its partner.
- All core histones have the structural motif of the histone fold. N- and C-terminal histone tails extend out of the nucleosome.
- H1 is associated with linker DNA and may lie at the point where DNA enters or exits the nucleosome.



The crystal structure of the histone core octamer is represented in a space-filling model

Abstract

Go to:

Eukaryotic chromatin is a combination of DNA and histone proteins. It is established fact that epigenetic mechanisms are associated with DNA and histones. Initial studies emphasize on core histones association with DNA, however later studies prove the importance of linker histone H1 epigenetic. There are many types of linker histone H1 found in mammals. These subtypes are cell specific and their amount in different types of cells varies as the cell functions. Many types of post-translational modifications which occur on different residues in each subtype of linker histone H1 induce conformational changes and allow the different subtypes of linker histone H1 to interact with chromatin at different stages during cell cycle which results in the regulation of transcription and gene expression. Proposed *O*-glycosylation of linker histone H1 promotes condensation of chromatin while phosphorylation of linker histone H1 is known to activate transcription and gene regulation by decondensation of chromatin. Interplay between phosphorylation and *O*-β-GlcNAc modification on Ser and Thr residues in each subtype of linker histone H1 in *Homo sapiens* during cell cycle may result in diverse functional regulation of proteins. This *in silico* study describes the potential phosphorylation, o-glycosylation and their possible interplay sites on conserved Ser/Thr residues in various subtypes of linker histone H1 in *Homo sapiens*.

Introduction

Go to:

Eukaryotic genome is packaged into a structure known as chromatin. The basic structural unit of chromatin called as nucleosome is composed of DNA and proteins [1]. The major proteins involved in chromatin structure are histone proteins. Histone proteins are of five types: H1, H2A, H2B, H3 and H4 [2-4]. Histone H1 is known as linker histone while the other four histone proteins are collectively known as core histones. This DNA-protein complex is the tempelate for a number of essential cell processes including transcription recombination, repair and replication. Histone H1 is located on the linker DNA that goes between the nucleosomes in chromatin structure [5]. Linker DNA which is associated with linker histone H1 interconnects core particles, varies in length, depending on species and tissue [6]. Organization of DNA into nucleosomes by histone proteins and folding of nucleosomes into higher-order chromatin structure is generally believed to compact DNA and make it inaccessible to transcription factors [7]. Linker histones H1 are necessary for modulating chromatin structure and function at multiple levels [8].

Communicated by Gerald M. Rubin, University of California, Berkeley, CA (received for review September 9, 1999)

Abstract

Centromeres of most organisms are embedded within constitutive heterochromatin, the condensed regions of chromosomes that account for a large fraction of complex genomes. The functional significance of this centromere–heterochromatin relationship, if any, is unknown. One possibility is that heterochromatin provides a suitable environment for assembly of centromere components, such as special centromeric nucleosomes that contain distinctive histone H3–like proteins. We describe a *Drosophila* H3–like protein, Cid (for centromere identifier) that localizes exclusively to fly centromeres. When the *cid* upstream region drives expression of H3 and H2B histone–green fluorescent protein fusion genes in *Drosophila* cells, euchromatin–specific deposition results. Remarkably, when the *cid* upstream region drives expression of yeast, worm, and human centromeric histone–green fluorescent protein fusion proteins, localization is preferentially within *Drosophila* pericentric heterochromatin. Heterochromatin–specific localization also was seen for yeast and worm centromeric proteins constitutively expressed in human cells. Preferential localization to heterochromatin in heterologous systems is unexpected if centromere–specific or site–specific factors determine H3–like protein localization to centromeres. Rather, the heterochromatic state itself may help localize centromeric components.

Control of Transcriptional Elongation

Hojoong Kwak and **John T. Lis**
Department of Molecular Biology and Genetics, Cornell University

Hojoong Kwak: hk572@cornell.edu; John T. Lis: jtl10@cornell.edu

Abstract

Elongation is becoming increasingly recognized as a critically controlled step in transcriptional regulation. While traditional genetic and biochemical studies have identified major players of transcriptional elongation, our understanding of the importance and roles of these factors is evolving rapidly through the recent advances in genome-wide and single-molecule technologies. Here we focus on how elongation can modulate the transcriptional outcome through the rate-liming step of RNA polymerase II pausing near promoters, and how the participating factors were identified. Among the factors we describe are NELF and DSIF, the pausing factors, and P-TEFb, the key player in pause release. We also describe non-exclusive models for how pausing is achieved by making use of high resolution genome-wide mapping of paused Pol II relative to promoter elements and the first nucleosome. We also discuss Pol II elongation through the bodies of genes and the roles of FACT and Spt6, the factors that allow Pol II to move through nucleosomes.

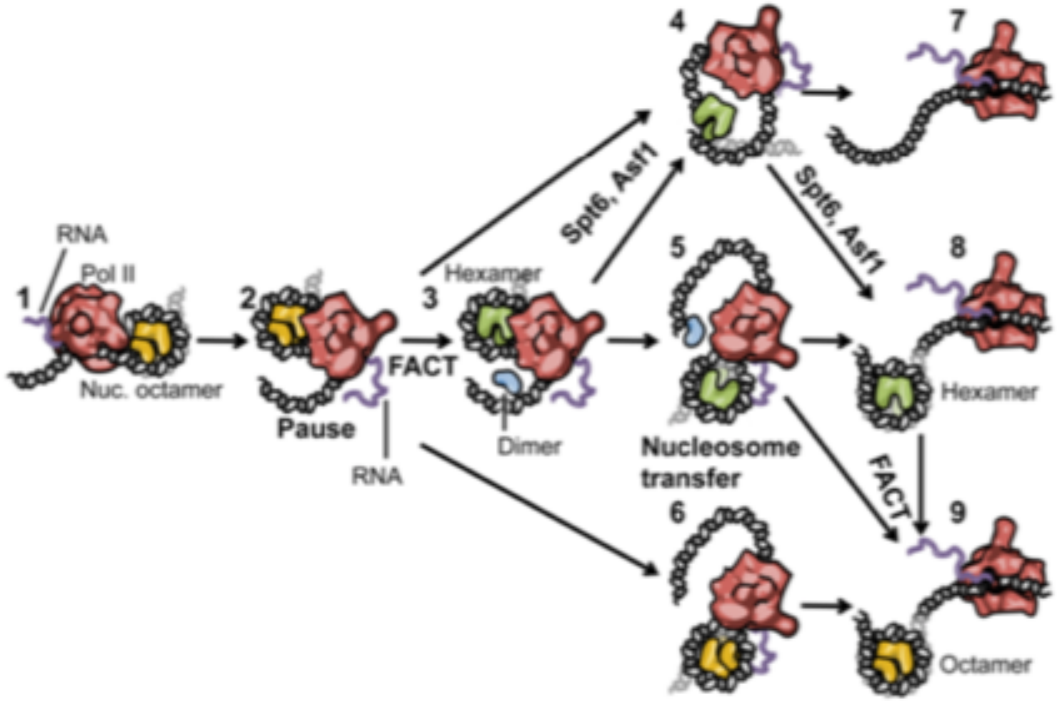

Figure 4. Pol II transcribing through gene body nucleosomes

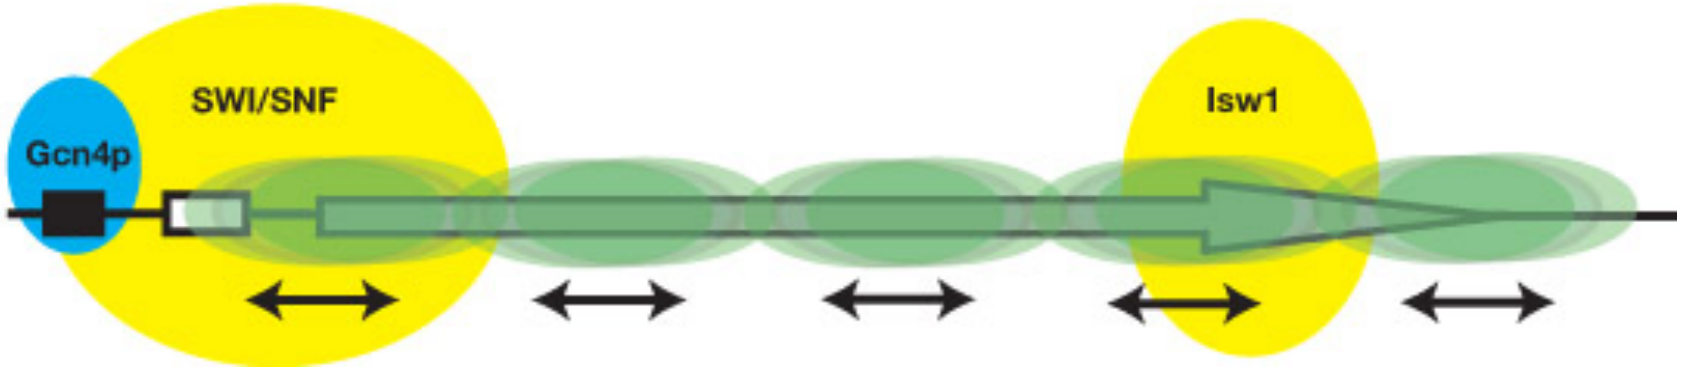
Pol II may use multiple mechanisms to get through a nucleosome, and not all the steps are used. Step 1, Pol II approaches and makes contact with a nucleosome. Step 2, the outer wrap of nucleosomal DNA can be easily unwrapped (17), and Pol II moves into the nucleosome near the dyad axis. Pol II active site is at around −40 from the dyad axis. The nucleosome binding is strong at this point and Pol II often pauses transiently (25, 52, 65). Step 3, H2A/H2B dimer is dissociated from the DNA and the nucleosome is now a hexamer. A dissociated dimer can still remain through its association with FACT and be re-deposited later (9). Step 4, H3/H4 core nucleosomal particle is evicted from DNA. H3 can remain associated and be re-deposited by Spt6 or Asf1 (13, 118) Step 5, nucleosome hexamer transfers upstream of Pol II while Pol II transcribes into downstream region. A looping intermediate may form during the transfer. Step 6, nucleosome octamer transfers upstream of Pol II, which can be facilitated by histone chaperones. Step 7, Pol II evicts the nucleosome by transcribing through it. Step 8, Pol II transcribes through the nucleosome leaving a hexamer. Step 9, Pol II transcribes through the nucleosome leaving an octamer.

Basal *HIS3* chromatin is static:

Dominant array with little remodelling activity.

Activated *HIS3* chromatin is dynamic:

Nucleosomes are in flux as they are continually mobilised into different arrays by the competing activities of SWI/SNF, Isw1 and other remodelling complexes.



Basal/unactivated HIS3 chromatin is static and shows a single dominant nucleosomal array with little remodeling activity (top panel) Basal/unactivated HIS3 chromatin is static and shows a single dominant nucleosomal array with little remodeling activity (top panel)

ABSTRACT

Mammalian genomes are folded into spatial domains, which regulate gene expression by modulating enhancer-promoter contacts. Here, we review recent studies on the structure and function of Topologically Associating Domains (TADs) and chromatin loops. We discuss how loop extrusion models can explain TAD formation and evidence that TADs are formed by the ring-shaped protein complex, cohesin, and that TAD boundaries are established by the DNA-binding protein, CTCF. We discuss our recent genomic, biochemical and single-molecule imaging studies on CTCF and cohesin, which suggest that TADs and chromatin loops are dynamic structures. We highlight complementary polymer simulation studies and Hi-C studies employing acute depletion of CTCF and cohesin, which also support such a dynamic model. We discuss the limitations of each approach and conclude that in aggregate the available evidence argues against stable loops and supports a model where TADs are dynamic structures that continually form and break throughout the cell cycle.

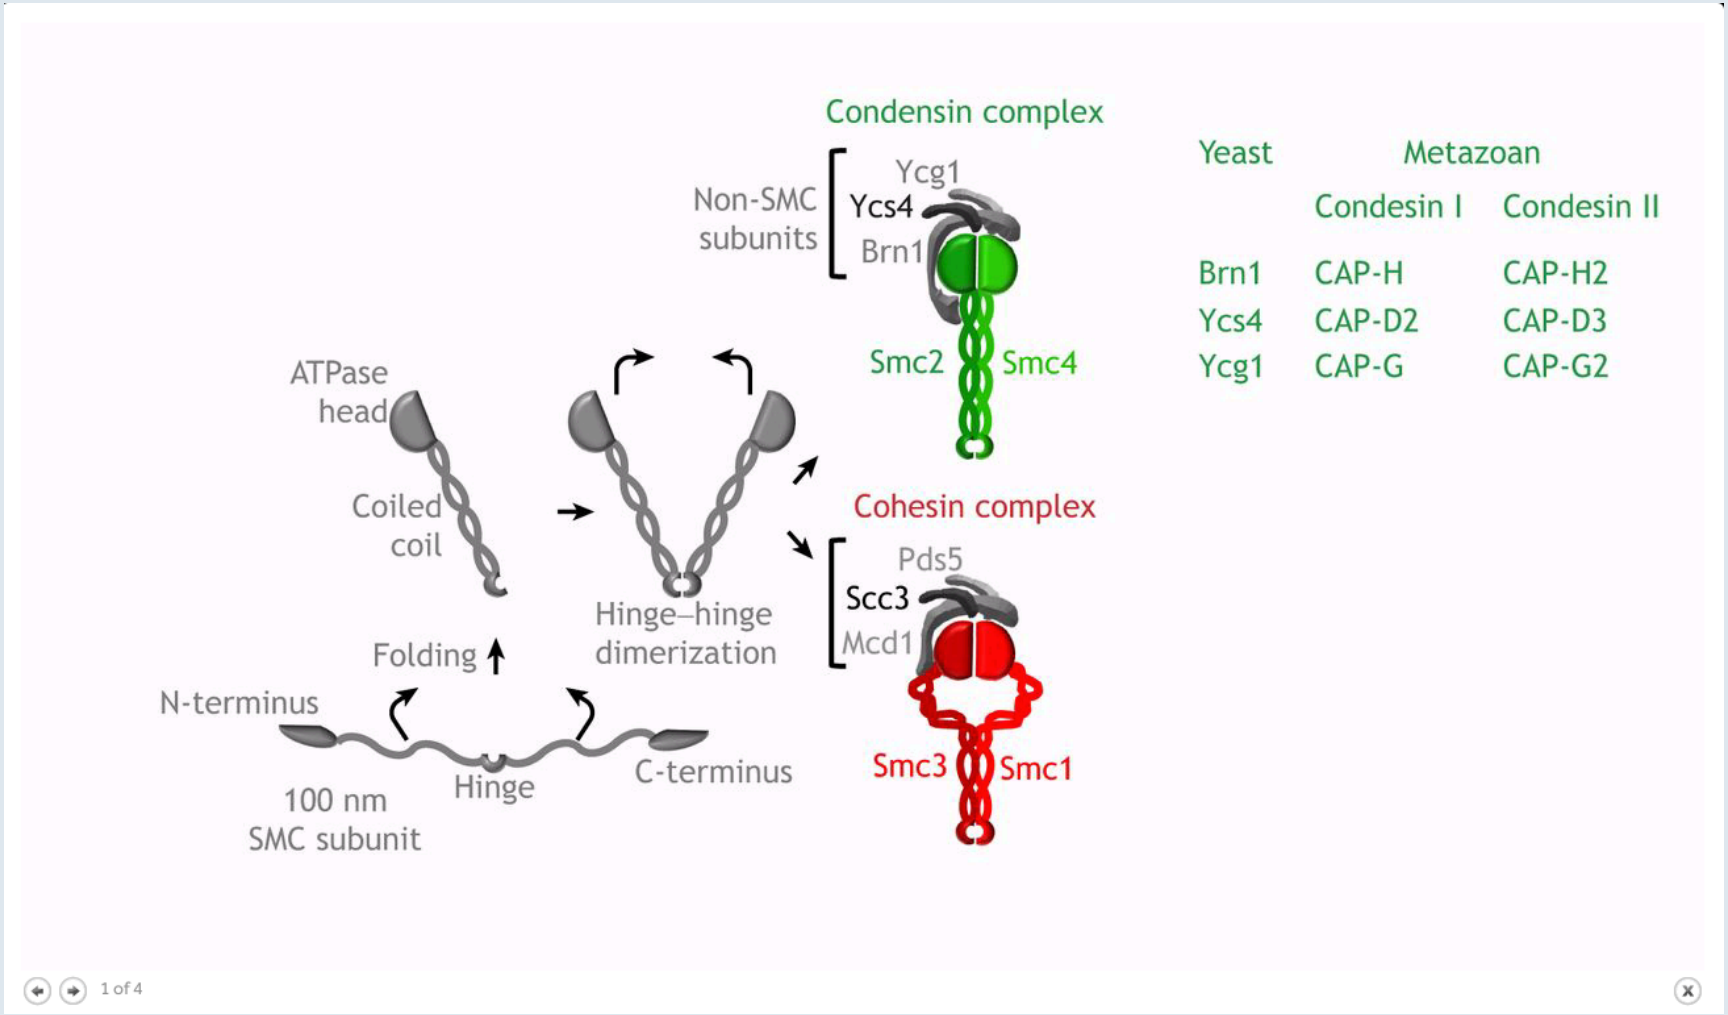
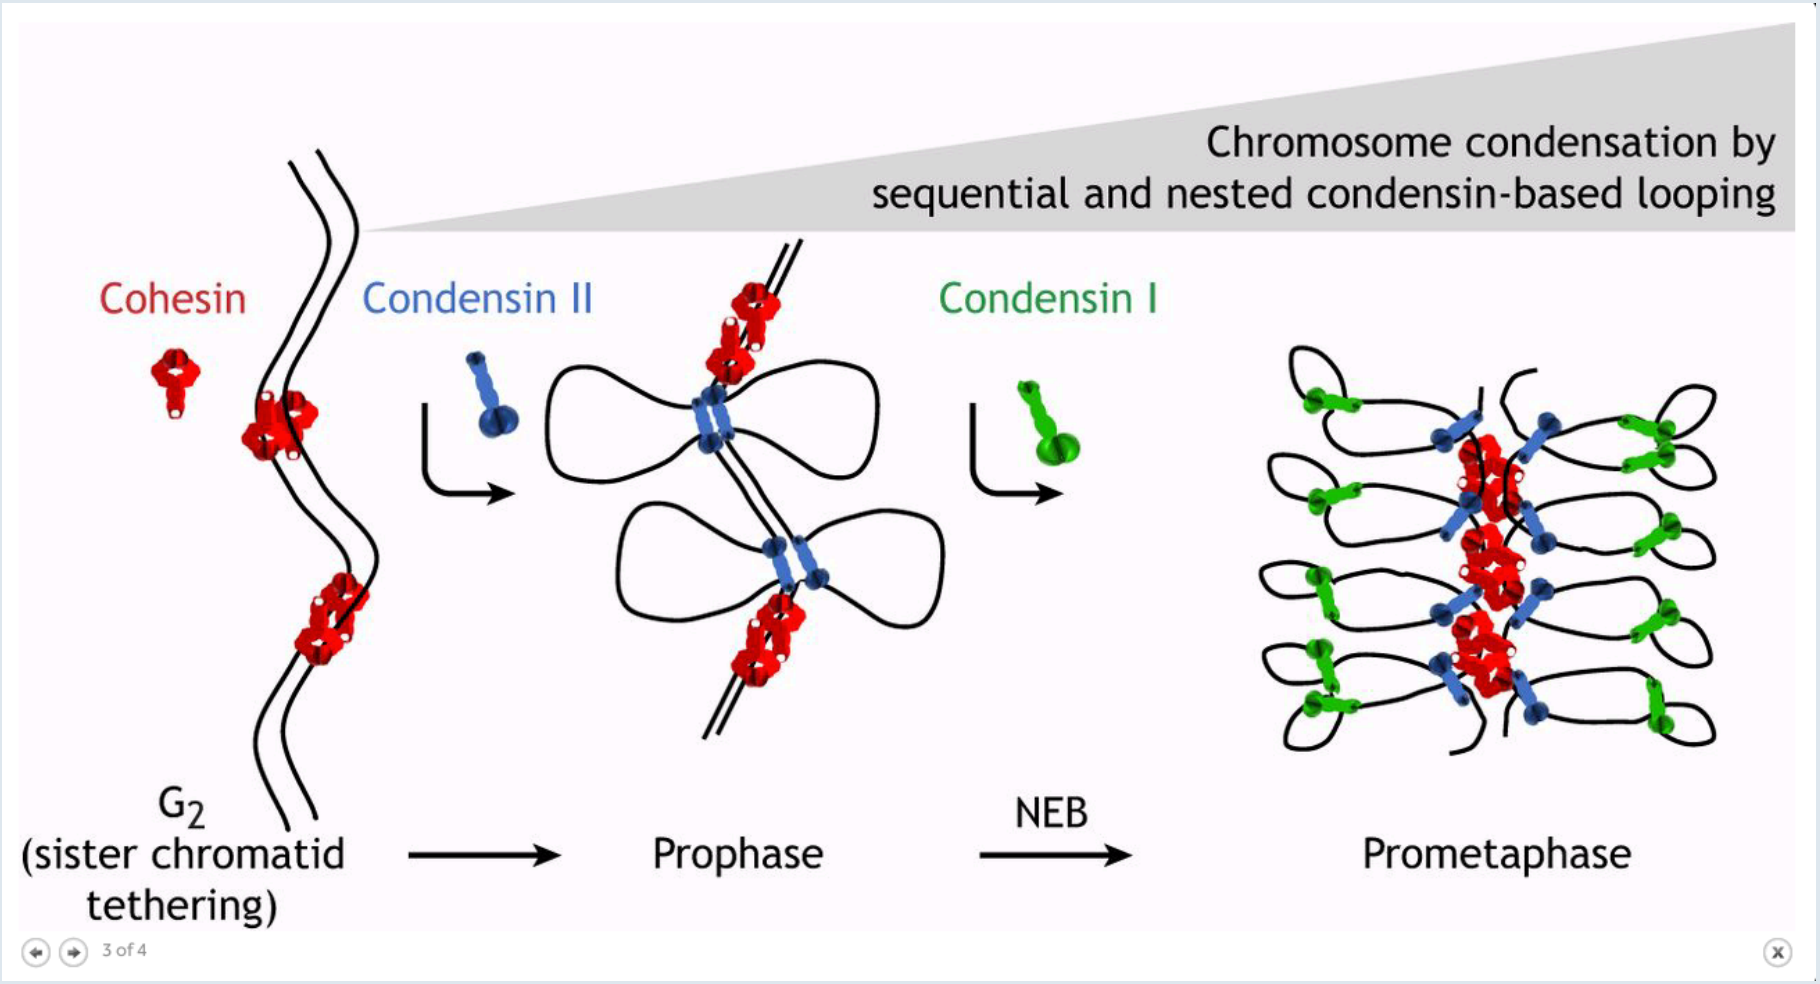
ABSTRACT

Condensins and cohesins are highly conserved complexes that tether together DNA loci within a single DNA molecule to produce DNA loops. Condensin and cohesin structures, however, are different, and the DNA loops produced by each underlie distinct cell processes. Condensin rods compact chromosomes during mitosis, with condensin I and II complexes producing spatially defined and nested looping in metazoan cells. Structurally adaptive cohesin rings produce loops, which organize the genome during interphase. Cohesin-mediated loops, termed topologically associating domains or TADs, antagonize the formation of epigenetically defined but untethered DNA volumes, termed compartments. While condensin complexes formed through *cis*-interactions must maintain chromatin compaction throughout mitosis, cohesins remain highly dynamic during interphase to allow for transcription-mediated responses to external cues and the execution of developmental programs. Here, I review differences in condensin and cohesin structures, and highlight recent advances regarding the intramolecular or *cis*-based tetherings through which condensins compact DNA during mitosis and cohesins organize the genome during interphase.



SMC assemblies. The stereotypical folding and dimerization of SMC subunits is shown in gray; 100-nm-long SMC proteins fold at a central hinge and allow for N- and C-terminal binding to form ATPase heads. SMCs dimerize predominantly through hinge-hinge binding but also head–head binding. Condensins (shown in green) are formed from Smc2 and Smc4 heterodimers that recruit the non-SMC subunits Brn1, Ycs4 and Ycg1 to form flexible rods (see Fig. 2). Cohesins (shown in red) are formed from Smc1 (SMC1a or SMC1b in metazoans) and Smc3 heterodimers that recruit the non-SMC subunits Mcd1, Scc3 and Pds5 to form flattened rings (shown) but can adopt other conformations, such as rods, open V-shapes or C-clamps (not shown). Yeast contain single copies of Brn1, Ycs4 and Ycg1, but metazoan cells contain paralogs, which give rise to unique subtypes termed condensin I (CAP-H, CAP-D2 and CAP-G, encoded by NCAPH, NCAPD2 and NCAPG, respectively) and condensin II (CAP-H2, CAP-D3, and CAP-G2, encoded by NCAPH2, NCAPD3 and NCAPG2, respectively). Metazoan cells also contain subunit paralogs (RAD21 or RAD21L for Mcd1, SA1/STAG1, SA2/STAG2 or SA3/STAG3 for Scc3, and PDS5a or PDS5b/APRIN for Pds5), but the assembly of non-SMC subunits into cohesin complexes is less well defined. Note that metazoan cells also contain Sororin, which is absent in yeast



Cell-cycle-regulated chromosome compaction by sequential recruitment of condensins II and I promotes the formation of nested loops. Replicated sister chromatids are tethered together by cohesins (red). During prophase, condensin II (blue) binds DNA and extrudes loops. After nuclear envelope breakdown (NEB), condensin I (green) binds the looped DNA and forms new loops that are nested within the condensin II-generated loops. As cells progress into late prometaphase, DNA loop extrusion and compression of the helical scaffold continues. Not shown is the role for cohesin in generating cis-based compaction, which also promotes chromosome condensation.

A pathway for mitotic chromosome formation
